typical example of this group, but the so-called paralytic ileus of peritonitis is usually included. Where a vascular occlusion is the cause of symptoms, a wide resection of intestine may be called for, and the results are often surprisingly good.

Whilst adynamic post-operative ileus may, and probably does, occur, it should never be diagnosed until an organic cause for the symptoms has been definitely excluded. Ever since it was possible, some seventeen years ago, to show experimentally that a fatal obstruction may result from recent and apparently trifling adhesions of the small intestine, an organic cause has been suspected in all these cases and has usually been found. As such post-operative obstruction, usually following operation for acute appendicitis, is associated with a healing peritonitis, it is the more important to recognize it and deal with it on rational lines. In some cases this will be by reopening the abdomen and freeing the adhesion. In the majority, however, a high jejunostomy of the abdominal tube type is the easier and safer procedure and is a truly life-saving operation.

Acute Obstruction due to Carcinoma of the Colon

When acute obstruction has finally supervened in an untreated case of carcinoma of the colon the initial surgical operation should be on the simplest lines. In an old subject with a palpable growth in the pelvic colon the two- or three-stage Miles operation has much to commend it, and offers less risk to life than any other surgical measure. I consider it unfortunate that this operation should have fallen into disuse, as its results compare very favourably with those of all other operations for carcinoma of the pelvic colon complicated by either subacute or acute obstruction.

In all other cases a preliminary "blind" cecostomy under local anaesthesia is undoubtedly the operation of choice.

GENERAL DISCUSSION

Mr. ERNEST CORWELL (Croydon) said that his contribution to the discussion was concerned with a clinical group of cases of acute intestinal obstruction of which he had had personal experience, and which seemed to be of importance—namely, acute intestinal obstruction occurring in elderly people due to causes other than carcinoma. The following table, which represents a grouping of cases met with by the speaker, was not claimed to be a complete and exhaustive list of pathological possibilities.

Acute Intestinal Obstruction

A Primary (causes arising in bowel itself)	
1 Developmental	Case 1
2 Inflammatory (local)	Case 2
3 Adenoma	Case 3
B Secondary (causes outside bowel)	
1 Appendix complications—	
Subacute	Case 4
Chronic	Case 5
2 Tuberculous disease—	
Plastic peritonitis	Case 6
Caseous glands	Cases 7 and 8
3 Latent femoral hernia	Cases 9, 10, 11

The following were briefly quoted as examples and illustrative cases.

Case 1—A man aged 72 seen in consultation with Dr. Genge at Croydon General Hospital. He showed the symptoms and signs of small intestine obstruction. On laparotomy a volvulus of ileum arising in connexion with a Meckel's diverticulum was found. The patient recovered.

Case 2—A lady aged 63 seen after several days subacute obstructive symptoms when the case had become urgent. Clinically the case resembled one of a left-sided appendicitis with obstructive symptoms. At the laparotomy a patch of scarlet peritoneum was found on the outer aspect of the iliac colon. No diverticula were apparent. Beyond removing a chronically adherent appendix nothing was done and the patient gradually recovered.

Case 3—A man aged about 50 was sent into hospital with vomiting and constipation. On laparotomy, after separating adhesions in the caecal region further search revealed a lump in the terminal portion of ileum the size of a pigeon's egg. The patient made an uneventful recovery after resection and anastomosis. Microscopically the growth proved to be a simple adenoma.

Case 4—This case of acute intestinal obstruction (first seen several years ago), which was subsequently shown to follow a mild subacute appendicitis made a great impression on the speaker. The patient a general aged nearly 80 was seen by his doctor for a fortnight because of mild colic and occasional sickness. Finally the bowels became more obstinate until caecostomy no longer operated. At the laparotomy, at which Mr Cowell assisted, an inflamed appendix was adherent to the pelvic peritoneum allowing several feet of ileum to form a volvulus. In spite of resection the patient did not long survive the operation.

Case 5—In this case Mr Cowell referred to a *post mortem* specimen in which a long appendix was adherent by a fistulous opening at its tip to the ileum. There was no record of clinical symptoms.

Case 6—A man, aged 63, had been operated on by the speaker two years previously for ileo caecal tuberculosis. At the second operation there was universal tuberculous peritonitis and in spite of a caecostomy he sank and died. Clinically the case closely resembled one of growth, and might have been mistaken for such had the previous history not been known.

In the two following cases obstruction resulted from adhesion of bowel or its mesentery to an old calcified tuberculous gland.

Case 7—A frail delicate lady, aged 76, seen in 1919 in private practice. After four days pain constipation, and vomiting it became obvious that laparotomy could no longer be avoided. Delay was sanctioned here because the patient had recovered from similar attacks over a period of many years. At operation a small stony gland was found adherent to the ileum. On one side there was rabbit's intestine" and on the other a "bicycle tyre" effect. A temporary enterostomy was performed and five days later a resection and closure. This patient was still alive and well.

Case 8—A man aged 50 regarded as a case of small intestine obstruction. Here a coil was tightly adherent to a calcified tuberculous gland. He recovered after operation.

Case 9—As a resident many years ago Mr Cowell had seen a case of latent femoral hernia with symptoms of abdominal pain, vomiting, and constipation that was withheld from the surgeon for a week because the patient's general condition remained fairly good. The abdomen was repeatedly examined but the femoral region escaped notice. When operation was finally sought it was unsuccessful.

Case 10—Recently he had seen two similar cases in elderly women. In these cases the doctors knew the patients had small femoral hernias but for some reason did not associate the symptoms with the real underlying condition.

Case 11—This case, Mr Cowell was told was probably a medical one—possibly ptomaine poisoning—and there was no urgency. However, he saw the patient at once and from the symptoms came to the conclusion that the small intestine was concerned, and on routine examination found a femoral hernia the size of a small gland. At the operation a partial lateral enterocoele was discovered. The patient recovered.

In drawing attention to this class of case and quoting from his own experience, the speaker's hope was that patients might be given the benefit of the doubt where the question of operation might be difficult to decide, remembering that carcinoma of the bowel was not the only diagnosis in old people, in cases of intestinal obstruction.

Mr R. P. ROWLANDS (London) had, with the help of his surgical registrar, Mr B. L. Laver, investigated the notes of the 304 cases which were admitted to Guy's Hospital during the five years 1920-24. The total mortality was 31.5 per cent, if the cases of intussusception and strangulated hernia were excluded the mortality would be considerably higher. He agreed that delay in diagnosis and errors in treatment were chiefly responsible for this high mortality. It was difficult, however, to assess the blame for the delay, for everyone was concerned in it—the patient and his friends, the general practitioner, the consulting physician, and the surgeon. The difficulties of diagnosis were great, especially when intestinal obstruction followed a few days after a laparotomy, it was very tempting then to wait and hope that the symptoms might be due to paralytic distension, and thus to throw away the best chance of overcoming genuine obstruction by operation. They should not add to the difficulties by giving sedatives or purgatives, which often did much harm, if two enemata failed to act when there were symptoms of intestinal obstruction, he thought it best to proceed to immediate operation. It was a mistake to waste time on refinements of diagnosis. The essential thing was to decide at once whether an operation was or was not necessary. He never used the word "exploration," for it frightened the patient and might make him defer operation. At the operation itself skill, gentleness, judgement as to what to do, speed and accuracy of work, were priceless. The early cases did extremely well without lavage of the stomach or any

drainage of the intestine, the later cases required large and drainage of the bowel, and for this purpose he preferred lateral anastomosis in most cases, reserving valvular enterostomy for the graver ones. He performed this after the manner of Witzel's gastrotomy, and brought the tube out through the great omentum after C. H. Mayo's method. He also sewed the tube into the bowel and used a slip knot so that the tube could be removed at any moment, generally forty-eight hours after the vomiting had ceased. In these circumstances, when the tube was removed, there was hardly ever any leakage and no need for an operation for closing a fistula. Some fifteen years ago he saved the life of a house-surgeon in this manner when he was very ill indeed with late intestinal obstruction. Similarly, in late cases of acute obstruction of the large intestine, he used a valvular enterostomy with a rubber tube half an inch in diameter. This was much better than a Paul's tube and could be retained several weeks without any leakage. It was not removed until about ten days after the subsequent colectomy. Saline infusions were very valuable in all these cases and should be used frequently. He mentioned an interesting case.

A small girl, operated on for acute obstruction was found to have a large hairball in her ileum, it was successfully removed. The child came into hospital again, some weeks later, suffering from a milder attack of intestinal obstruction due to the same cause. This was relieved by a purgative, a small hairball being passed. After the first operation the child had been warned not to eat her hair, but took little notice, after the second admission therefore, instructions were given to keep her hair cropped short.

Mr MACPHER (London) presented the figures from St Thomas's Hospital, which totalled 336 for the five-year period. The number of cases seemed to be small when compared with an approximate total of 33,000 patients admitted to the medical and surgical wards during the five years reviewed. He was indebted to Mr C. V. Patrick, surgical registrar to the hospital, for the collection of the particulars, he had been careful to include in the figures only those examples in which the symptoms of intestinal obstruction could properly be called acute. It was found that the separating line from cases of chronic obstruction was sometimes difficult to define. The criterion adopted to justify inclusion in the figures presented had been the presence of persistent vomiting associated with acute colicky pain in the abdomen. In considering the results as a whole, attention was drawn to the fact that they represented the work of surgeons who could only claim a moderate experience in this class of work. The greater proportion of the cases had been operated on as urgencies, and in consequence the junior staff had been responsible for most of them. On account of the diversity of the conditions dealt with it was out of the question to detail the operative procedures employed. In general they might be stated to have been on classical or old-fashioned lines. His figures did not furnish any information on the value of jejunostomy for acute obstruction, as it was performed in only one or two cases. In view of Sir William Taylor's depressing statement that the results of the treatment of intestinal obstruction had not improved during the last thirty years, he thought it might be of interest to compare some of the recent figures of St Thomas's Hospital with those published in the hospital reports over a similar period twenty years ago—namely, 1900-4. This he had done for three of the larger groups—namely, intussusception, strangulated hernia, and carcinoma of the large bowel. The results of the treatment of acute intussusception in these two periods were tabulated as follows.

Idiopathic Intussusception in Children aged 5 years or under (1900-4 and 1920-24)

	Cases	Deaths
1900-1904	67	27=40.3 per cent
1920-1924	102	9=8.9 "

For 1900-4 out of a total of 84 cases 67 occurred in children of 5 years or under, and the mortality for this group was no less than 40.3 per cent. The improvement in the results of this class of obstruction was due, he thought, to the earlier period at which operation had been undertaken, though no doubt a clearer appreciation of the operative technique had been another favouring factor.

In the other two conditions responsible for a considerable

incidence of acute obstruction there was not such a striking improvement in the results. Taking first strangulated hernia in the figures presented for inclusion in the total only those cases of strangulated hernia in which there was acute obstruction had been included, so this figure was not obtainable for 1920-4, he had taken all cases of strangulated hernia for the five-year periods in order to prepare a tabulated comparison.

Strangulated Hernia (all cases)

Class	1900-4	1920-24	1900-4		1920-24		Deaths	
			R	D	R	D	1900-4	1920-24
Intestinal	229	83	205	24	77	6	per cent 10.4	per cent 7.2
Femoral	131	95	106	25	85	11	15.6	11.4

R = Recovered D = Died

In regard to carcinoma of the large bowel as a cause of obstruction, it was noticeable how small a number of cases justified their inclusion under acute obstruction. From 1920-24 there were only 28 patients, 17 of whom were relieved and 11 died—a mortality of 39.2 per cent. During the same period 293 cases were admitted into the hospital with carcinoma of the large bowel without acute obstruction, of whom 234 patients were discharged relieved and 59 died—a mortality of 20.1 per cent. In the 1900-4 period 112 cases of carcinoma of the large bowel were operated on for obstructive symptoms with a 23.2 per cent mortality. These comparisons suggested that surgeons and general practitioners had not been quite so unprogressive during this century as Sir William Taylor would have had them believe, but it was admitted that the figures showed that there was still plenty of room for improvement. He did not think he could usefully analyse the methods and results in the smaller groups on account of the limited number that fell within them. They served to swell the tabulated table which Mr. Soutter was to present later.

Professor A. PRIMOSE (Toronto) gave some details regarding the work of his junior colleague in Toronto, Dr. Costain. He was unable to give exact figures to indicate the clinical results which had been obtained, but these were available in the literature. Dr. Costain's work consisted of a series of experiments on dogs. Peritonitis was induced by ligaturing the appendix and its mesentery and by introducing septic organisms at the seat of ligation. After peritonitis had been induced the life of the animal was saved by opening and draining the thoracic duct in the neck. Control animals, in which the thoracic duct was not drained, died. Several attempts had been made to apply this method in the treatment of peritonitis in human subjects, with varying success. In the children's hospital in Toronto he thought some seven or eight cases of pneumococcal peritonitis were submitted to the procedure. These cases were all considered hopeless in the absence of operative treatment. A certain number of these patients recovered after operation. He regretted that he was unable to give exact figures, but could state that in these cases the pneumococcus was recovered in the discharges from the thoracic duct fistula, in that respect they differed from the case reported by Mr. Wilkie, in which the discharges were sterile. The work of Dr. Costain was of very great interest. Its specific clinical value was not yet determined but it was hoped it might prove of service in certain types of general peritonitis. Mr. Wilkie had referred to the value of the administration of saline intratubally in acute obstruction, and had suggested that the beneficial results were due to the administration of chlorides where there was chloride deficiency rather than to the correction of a condition of dehydration. A considerable amount of work had been done in Toronto on the hypothesis of the diminution in chlorides, most of this investigation had been carried on in the clinic of his colleague Dr. F. N. G. Starr. The chloride was administered intravenously, about ten ounces of a 15 per cent solution of sodium chloride being given. The beneficial results of such treatment were truly remarkable. Further, it had been found that 3 drachms of ammonium chloride

administered per rectum would occasionally improve promptly the condition of a patient, so that an operation might be undertaken in cases which prior to such treatment had appeared inoperable. Lastly, he called attention to the part played by the ileo-caecal sphincter in obstruction of the large bowel. When that sphincter was competent the large bowel might become enormously distended if the obstruction was low down, as, for instance, in the sigmoid or rectum. It was astonishing how the distension might in many cases be restricted to the large bowel, which might be ballooned to large size. On the other hand, if the ileo-caecal sphincter were incompetent, as was frequently the case, the distension spread rapidly to the small bowel and as it ascended the symptoms of obstruction became more marked and much more grave.

Mr. REYNOLD M. VICK (London) presented the statistics from St. Bartholomew's Hospital for the period 1920-24 inclusive. The cases treated over that period numbered approximately 300, and showed a total mortality, under all headings, including obstruction due to malignant disease, of 28 per cent. The detailed figures under each group coincided so exactly with those of the mass statistics to be submitted later by Mr. Soutter that it would be mere waste of time to consider them very closely. They were no better, which was disappointing, and no worse, which was consoling, than any other of the statistics to be presented. Whichever way they looked at these figures, they showed a distressingly high mortality considering that acute intestinal obstruction—apart from the cases due to malignant disease—should have hardly any mortality at all. Mr. Vick then put forward one or two suggestions as to ways in which they might improve their results. First and foremost, a careful study of the details of the history of these patients showed, as Sir William Taylor had said, that the one great outstanding reason for the high mortality was that the patients arrived in the surgeon's hands too late. It was true that, among the late cases, there came across brilliant exceptions, where, as the result of one or other of the treatments described, the patient's life had been saved but they were the exceptions, whereas, among the early cases, the exceptions were the ones who died. Sir William Taylor had stated, in no uncertain manner, one explanation of the late arrival of these patients in the operating theatre, where lay their only hope of life. But surely there were many others. They must all have come across many cases in which the doctor himself was called in too late. It seemed that when this occurred the explanation lay in the very nature of the emergency itself. A patient who developed in acute intestinal obstruction—say as the result of a bad—might suffer in the early hours from intense pain of a colicky character with some initial vomiting, but if the strangulation was complete gangrene supervened and the pain abated and disappeared. Any patient judged the seriousness of his condition from the amount of pain he suffered which was but natural. When his pain disappeared he might wait two, three, or even four days until the classical signs of obstruction were present—the vomit becoming stercoraceous and profuse and the distension great before he called in the doctor. It was difficult to say who was to blame in these cases—presumably the patient, but he at any rate often paid the extreme penalty. They could not expect much improvement under this heading until, with the spread of knowledge, patients began to realize that surgeons had other interests than “to cut them up.”

Another suggestion that would seem to be of value was the establishment of a system of observation beds in hospitals—beds into which patients could be admitted, without all the formalities of admission to hospital while the diagnosis of their condition was still in doubt. It would be a great thing for practitioners to know that there were such beds into which they could send their patients before the diagnosis of obstruction, though probable, was actually made. It would be a good thing for patients to know that their admission to hospital did not mean an operation provided their symptoms could be cleared up in any other way. If a couple of enemata should relieve the obstruction the patient would find

presented great difficulties, but considering that a large proportion of the patients were young the mortality of over 30 per cent was high. Carcinoma and gall stones on the other hand, only appeared late as causal factors, becoming most prominent in the sixth and seventh decades. The incidence of carcinoma in the left side of the colon was well shown, this side being affected more than five times as often as the right. The high mortality of gall-stone obstruction was partly accounted for by the fact that most of these cases occurred after the age of 60, but an important factor must be the delay which often took place in diagnosis shown in the fact that out of 28 cases only 3 were operated upon before the fourth day.

Mr GREY TURNER (Newcastle-on-Tyne), in presenting the statistics from Newcastle-on-Tyne, expressed his great indebtedness to the surgical registrars who had taken so much trouble in going over the notes and in getting the information required. He said that the figures indicated only too clearly that intestinal obstruction was still a very dangerous condition. This was well illustrated by a reference to those for strangulated hernia, which showed that where operation for radical cure could be performed with a mortality of considerably less than 1 per cent, the mortality in strangulated cases was still something over 20 per cent. In his experience he had seen no real improvement in the treatment of the cases which had been allowed to go on to the stage of toxemia. In this connexion he said that the picture of intestinal obstruction in the mind's eye of the practitioner was still too often that of its later stages, and he laid stress on the importance of the earlier stages, in which there were practically no physical signs. How often one was told that the vomit had only just become fecal as though its presence was necessary before a diagnosis of obstruction could be made! He was reminded of one of Mr Simpson Handley's earlier papers in which he stated very forcibly that fecal vomiting should not be looked upon as a sign of obstruction, but as a sign of impending death. The enema test had been spoken of as a

help in the diagnosis, and he would like to mention the value of the erlenmeyer test. Over twenty years ago he first became familiar with this method and was a great believer in its value. Subsequently he sometimes felt that it was perhaps rather a shabby method of diagnosis, but it the present day he recognized its great practical utility. The plan was to give 4 or 5 grains of erlenmeyer in 1/2 grain doses every half-hour, followed at the end of the course by another enema. This either succeeded in clearing away the obstruction or made the symptoms so definite that the diagnosis was perfectly plain, and treatment by operation could be commenced without the slightest hesitation. He wanted to draw attention to the cases in which vomiting was a marked feature, for in them the exhibition of a general anesthetic was so often fatal he most vividly remembered cases in which at a necropsy the fecal matter could be squeezed from the lungs like a wet sponge. Preliminary stomach washing sometimes sufficed, but, generally speaking, it was necessary to operate with some type of local or regional anesthetic, and this was one of the most useful fields for such anesthetics. As a method of treatment enterostomy had been most disappointing, though as an adjunct it was sometimes extremely useful and valuable. But the discussion had wandered into wider fields, for one of the speakers had maintained that the public should be educated with regard to the symptoms of obstruction and urged to seek advice at an earlier stage. The President the previous day expressed the same idea with regard to the symptoms which might herald malignant disease of the stomach. Personally, he was not in agreement with this plan, and indeed he thought that anything of the kind would be, so to speak, riding for a fall. Diagnosis was always difficult and even with the greatest of care and the best intentions in the world there were many pitfalls which none of them could avoid. What, for instance, must be the comment of the public who visited a surgeon complaining of symptoms which they were told were not due to any organic lesion, and yet on the day after the consultation the presence of duodenal ulcer was confirmed by severe melena or is in

another instance, when a duodenal ulcer, supposed not to exist, perforated only a day or two after the patient had left the surgeon's consulting room? Or, again, what could be their answer when patients still frequently came with advanced malignant disease and who in the earlier stages had sought medical advice, only to be told not to worry about any lump unless the lump commenced to worry them? He felt very strongly that their efforts at education should be entirely limited to themselves. From this point of view much more might be done, and he felt that some one body—possibly none better than this Association—should issue leaflets to the profession, much as used to be done in the war, giving a summary of the latest information on certain conditions. This plan was being adopted in Italy, and he heard last year in the clinic of Professor Putti, in Bologna, that since the profession had been informed by means of such leaflets of the early symptoms and signs of congenital dislocation of the hip there had been a great increase in the number of cases which had been sent to the various clinics for treatment.

Mr A H BURGESS (Manchester) presented the statistics of the cases of acute intestinal obstruction admitted to the Manchester Royal Infirmary for the five years 1920-24 inclusive, for the compilation of which he was indebted to the registrars—Mr J A Panton and Mr N L Edwards. Two years ago, at the Portsmouth meeting of the British Medical Association, in opening the discussion on the treatment of obstruction of the colon, he had presented the Manchester Royal Infirmary statistics of acute obstruction for the ten years 1913-22 inclusive (*JOURNAL*, 1923, vol II, p 547). A comparison of these two series of statistics showed a definite improvement—the total mortality of 28.79 per cent in the earlier series being reduced to 23.5 per cent in the later, that of strangulated external hernia from 23.04 to 16.05 per cent, that of intussusception from 36.9 to 24.8 per cent, that of obstruction from non-malignant causes other than intussusception from 50.04 to 29.1 per cent, and that of obstruction from malignant growths from 35.22 to 28.52 per cent. This improvement was distinctly encouraging, although the mortality was yet very much too high. It was unfortunate that no general statistics of the Dublin hospitals had been presented to them, but he heartily congratulated Sir William Taylor on the very small mortality of his personal operations for acute intussusception (3 deaths in 81 cases—that is, a mortality of 3.7 per cent). If these could be taken as a sample of the operative results of acute intestinal obstruction in general in Dublin, then it was obvious that the general practitioners and physicians of that fair city must be supplying the surgeons with cases diagnosed at an unusually early stage, and this seemed scarcely compatible with the very serious reflections cast upon them in this respect in the opening paragraphs of Sir William Taylor's remarks, certainly there seemed to be no justification for his "almost getting a rigor" when asked to operate in these cases. Only early diagnosis followed by the early application of surgical treatment could lead to any general improvement in the operative statistics, unfortunately there was a tendency, even yet, to wait for the textbook symptom of fecal vomiting to elude the diagnosis. The chief early features were the persistence of the vomiting, the cessation of passage of flatus, and the progressive abdominal distension without muscular rigidity; the importance of a steadily increasing distension of the abdomen could not be insisted upon too strongly. Distension was absent or slightly marked only when the site of obstruction was high up in the small intestine, and in these cases, fortunately for diagnosis, the vomiting was extremely persistent and very rapidly became feculent. He considered auscultation of the abdomen a much neglected diagnostic aid in obstruction cases. Having made a diagnosis of intestinal obstruction, the most important question next to decide was whether the obstruction was in the small or the large intestine. If they excluded the groups of strangulated external hernia and of intussusception, both of which were readily recognized—the former by a palpable swelling at a hernial orifice, the latter by its age of incidence and its very characteristic signs—then the chances were about equal as regards the small bowel or the colon. In the paper referred to pre-

viously he had gone fully into the diagnosis between these, which he believed could be correctly made in the majority of cases. The criterion was the condition of the cecum: if this was visibly distended, or, failing this, if it could be definitely felt to harden and soften alternately under the examining fingers ("palpable peristalsis"), then the obstruction was distal to it. Where the site of obstruction could be located in the colon but was not more exactly known, and where there was no special reason to suspect volvulus or internal strangulation, he still considered, as he had advocated at the Portsmouth meeting, that the sole immediate operative procedure should be cecostomy performed under nitrous oxide or local anaesthesia ("blind" cecostomy). For those cases where the site of obstruction could be assigned to the small intestine, or where it was uncertain whether it was in the small or large bowel, he thoroughly agreed with the treatment outlined by Sir William Taylor for each of the three stages of the general condition of the patient. He made special reference to the high mortality attending obstruction from impacted gall stones: the Manchester statistics included 7 cases with 3 deaths—a mortality of 42.86 per cent. The actual operation in these cases was technically easy and of short duration, the mortality was due partly to the age of the patient, but mainly to the delay in recognizing the existence of obstruction, which at first might be partial only. In two cases he had found two large gall stones impacted at different levels in the ileum—a condition easily overlooked unless the possibility was borne in mind. If a gall stone which ulcerated through into the duodenum succeeded in passing the ileocecal valve it was not likely to cause obstruction in the colon. But, as happened in two of the Manchester cases, a large gall stone might ulcerate from the gall bladder into the transverse colon and become impacted in the narrower sigmoid colon.

Sir WILLIAM TAYLOR, in a brief reply, said that owing to his own eldest son having suffered from an intussusception at the age of 8 months he had taken a particularly keen interest in this form of obstruction, and had used every opportunity of impressing upon the general practitioners in his neighbourhood the unmistakable symptom of this disorder. He had been rewarded by getting his cases at an earlier stage than most surgeons, and to this he attributed the low mortality in his series.

Mr A RENDLE SHORT (Bristol) said that his series called for little remark. The total number of cases, including strangulated hernia, was 277, without strangulated hernia 137. The general mortality, including the strangulated hernia cases, was 31.4 per cent, and without them it was 41 per cent. This was rather higher than the general average, which was accounted for by the remarkably small number of cases of intussusception. This only in part represented a real difference in the incidence of this disease in Bristol as compared with London, as many of the children with intussusception were treated at a children's hospital. Probably, however, there were fewer cases in proportion. Although the figures were not nearly as good as they would be if patients were operated on as soon as a diagnosis could be made, they were much better than they used to be. He had published in the *Index of Prognosis* collections of statistics from various hospitals in past years which showed a general hospital mortality, both at the Bristol Royal Infirmary and elsewhere, well over 50 per cent (for acute obstruction, not including strangulated hernia).

Mr S T IRWIN (Belfast) communicated the Belfast figures. He said that they numbered 155, and showed a gross mortality of 38.7 per cent over the whole series. They were quite impenetrable, and had been extracted from the hospital records by one of the surgical registrars. They comprised all those cases which had been admitted to hospital with the diagnosis of acute intestinal obstruction or had subsequently been so diagnosed. A few of the patients had not been operated upon. Even in cases fatal without operative treatment such a death rate was little short of appalling. Figures for acute intestinal obstruction were sought which might give a standard for comparison, but with the time at his disposal he failed to find

such. He had therefore to fall back on the figures in other abdominal diseases, and took those for acute appendicitis and for perforations of the stomach and duodenum. Taking acute appendicitis first, he found that in over 236 patients operated on in 1924 there was a mortality of 3.6 per cent, and in 1922 in over 312 cases a mortality of 3.2 per cent. He compared these with Love's, published in the *British Journal of Surgery*, which showed a mortality of 5.4 per cent over 312 cases, and with St. Thomas's Hospital cases—first a series of 214 cases with a mortality of 4.2 per cent, and secondly, with a series of 1,418 with 92 deaths, a mortality of 6.5 per cent—and found that the Belfast figures for acute appendicitis compared favourably with those of other schools. In 147 cases of perforations of the stomach and duodenum during the five years 1920-24 there was a mortality of 15.6 per cent, which agreed exactly with the figures published by Grey Turner in 1919. Judging, therefore, by these results it was fair to assume that the abdominal surgery at Belfast was at any rate average.

What mortality might reasonably be expected in cases of acute intestinal obstruction? The statistics quoted by Burgess at the Annual Meeting at Portsmouth in 1923 gave a mortality of 32.2 per cent over a series of 199 cases of acute intestinal obstruction in the colon. The Belfast mortality was markedly in excess of this, he therefore must refer to one or two general considerations which, he imagined, had had some influence on these figures. First of all, during the whole period of 1920-24 Belfast was under curfew regulations, and for a considerable part of the time active fighting was going on in the streets. This had kept the hospital working at high pressure on gunshot wounds. At times its resources in operators and in materials had been almost exhausted. The medical and municipal services had been disordered, and the arrival of many cases was postponed for at least twelve hours—a delay always serious and oftentimes decisive in a case of acute intestinal obstruction. Again, the figures given by Burgess dealt with operation cases only, whilst the figures used for the present estimation referred to the total admissions, and included cases moribund on arrival or practically hopeless so far as operation was concerned. In other words, it was the death rate among all cases "admitted" and not among those sufficiently well to undergo operation.

He wished also to bring to the notice of that Section the considerable group of unclassified cases, which numbered 17 out of a total of 155. In these cases no information was obtainable from the notes as to the actual pathological condition beyond that they were admitted as cases of obstruction. Several patients were too ill for operation and no necropsies were made. Out of these 17 patients only 3 recovered. It seemed hardly fair in an otherwise small series to include these in the figures, but they were there and could not be disregarded. It was clear that they were due to wrong diagnosis in the early stages of their illness. If these cases were excluded the Belfast results would give a mortality of 33.3 per cent over 138 cases. The Royal Victoria Hospital, Belfast, was the surgical centre for the whole of the North of Ireland, and received many cases from a radius of fifty miles and over. It was not unusual to find patients with perforation or obstruction who had been brought in by ambulance over this distance, many of these had already been ill for days. Some had even been admitted to a provincial institution in the first instance, and only transferred to Belfast later. It was notorious how readily shock and collapse were produced, how the patient's general condition deteriorated (and consequently how operation risks increased) as the result of disturbance in all cases of abdominal emergency. Another factor which must influence the result (a factor which he imagined applied to many other hospitals) was that the bulk of these operations had been performed by assistant surgeons or by surgical registrars, only a very small proportion coming under the full surgeon. Ability and technical skill counted for much in cases of acute intestinal obstruction (especially in the later stages, but judgement and experience were even more necessary). Again, many of the operations were done at night, when assistance was limited, a house-surgeon acting as anaesthetist and an unqualified resident assisting. This state of affairs denoted their failure to

appreciate the undoubted gravity of all such cases. Further, intussusceptions had been excluded from their list. They showed a percentage mortality less than the average, and their absence therefore affected his list unfavourably. Belfast could not compete with the figures of Sir William Tynor, but then figures showed a percentage mortality lying between 12 and 15. When due credit had been given, however, to all these points he could not but be disappointed to find a percentage mortality of over 30 even in cases of such undoubted gravity, one therefore wanted to examine the factors which decided for life or death of the patient. Of his cases 10 per cent were over 70 and 20 per cent over 60, probably a similar experience occurred in other hospitals also. A certain mortality must be expected in the later decades of life from that fact alone, and more especially, as in acute obstructions, where toxæmia was present. Secondly, the time factor which was probably of supreme importance in settling the result in any particular case, was important also from another viewpoint—namely, it was a factor which could and must be influenced, first by educating the public and afterwards by educating the profession.

The figures revealed that 50 per cent of all the cases had been ill for two days or more before admission to hospital. How could this delay be mitigated, and who was responsible for it?

1. The responsibility fell in the first instance upon the patient and his friends. Delay from this source could be modified only by the education of public opinion. The public must be taught to understand that abdominal pain was never normal, that it was never devoid of danger until so declared by a medical man—that it was, in fact, the danger signal of disaster whose timely recognition might mean a happy issue but whose neglect might mean the untimely death of the patient. Amongst rural populations, such is that of Northern Ireland, procreation was very prevalent. It was due to the failure of uneducated persons to recognize symptoms as serious (the pain and discomfort they could bear with equanimity), and to the long distances many of them lived from medical aid. From his experience of these cases the duration of symptoms was often considerably greater than the patient and his friends were willing to admit.

2. Practitioners must be educated to recognize abdominal disease earlier. He was told that the effect of the Insurance Act in England had been beneficial in this respect, but in Ireland this was still lacking. The question was primarily one for the schools, for the British Medical Association and its Branches, and for all medical societies. Improvement had doubtless taken place in the direction of early diagnosis both in perforations and in appendicitis, which were nowadays recognized at the doctor's first visit, and he felt that in the case of acute intestinal obstruction something, at least commendable might be attained. He believed that delay was often due to the administration by the practitioner of a hypodermic injection of morphia—a practice wholly unjustifiable until a definite diagnosis had been arrived at. Nor must he wait for vomiting to become free before making his diagnosis. He recalled being asked several years ago to see a case of acute obstruction by a doctor, who said he felt sure of his diagnosis as he had been watching the case for a week and vomiting was now free!

When the responsibility of the surgeon for these figures was considered it was only fair to say that treatment of acute intestinal obstruction was nothing but standardized, it was the exact operative technique in such diseases—cancer of the breast, gall stones, cancer of the uterus, etc. The latter diseases were much less fatal than acute intestinal obstruction, the speed of the operation counting for nothing as compared with its importance in a case of obstruction. He felt that the anxiety to do a complete operation was responsible for many of the deaths in this disease, and that the value of local or spinal anaesthesia, enterostomy, and the two-stage operation was insufficiently recognized. Why were hospital results so much worse than those treated privately? Was it not that under each of these heads, private cases showed a marked advantage? In 113 out of his series of 155 cases the small intestine had been involved—a large proportion. Delay in operation was

more serious in the small intestine generally than in obstructions of the colon. Some of these were strangulations, often meaning gangrene, and therefore resection associated with toxæmia. Some were due to bands without gangrene. In both groups the mortality was high—in the former owing to the resection, in the latter it was certainly owing to toxæmia. In both the symptoms were easy to recognize early and almost pathognomonic. Diagnosis should be correspondingly early and the results of treatment good. But such was not the case. Half the cases in both categories were ill for two days or over. Apparently they did not yet fully understand the meaning of intestinal toxæmia. They still lost patients who should live, and sometimes, though less often, patients lived who appeared to be hopeless. At present Bonney's treatment or Sampson Hindley's gave the best results. He usually performed both an anastomosis and a low enterostomy if time and the patient's condition allowed. It was not usually necessary to close the opening in a case of this sort provided the anastomosis was free. Whilst they were often too late in applying treatment in some cases, and whilst they were not in doubt as to the correct procedure in others—for example, intussusception, external hernia, malignant disease of the colon (thanks to Burgess)—they still looked for light upon the others, and especially the internal strangulations.

Finally, he referred to the fact that the value of a complete *post-mortem* examination, which showed not alone how the abdominal symptoms were caused but also disclosed that the cause of death was often not abdominal, was insufficiently recognized. It showed them the dangers of the various complications and sequelae, the recognition of which was a valuable step towards their avoidance. Whilst had already been done for them in the operative treatment of gastric and duodenal ulcer by Moynihan, and what had been done by Burgess for obstructions of the colon, it was reasonable to suppose might yet be done even for a diverse group such as the internal strangulations.

Mr GEARY GRANT said that improvements in the statistics of acute intestinal obstruction could only be achieved by early diagnosis, and for the failure to diagnose in the early stage the textbooks were responsible. He was rather surprised in this discussion to find that strangulated hernia and large intestine obstruction were included. The prognosis in the former was very much better, chiefly, perhaps, owing to early diagnosis. It was also much better, as regards immediate results, in large intestine obstruction. Intestinal obstruction had, like all other abdominal emergencies, three stages: (1) the stage of invasion, (2) the stage of remission, (3) the final stage of toxæmia. It was because the symptoms of the final stage were stressed rather than those of the stage of invasion that there was failure to diagnose. The symptoms of the first stage were definite enough in most cases—sudden colic, initial vomiting, etc., but the one essential was absolute constipation, unrelieved by enemata and with the cessation of passage of flatus. It was the failure to evaluate the last symptom which was the cause of the policy of watching these cases. As in perforated duodenal ulcer a graph showed the rapidly rising mortality rate after the first twelve hours, so with acute intestinal obstruction. The factor which determined the fatal result was the distension of the proximal bowel, which paralysed it and produced multiple kinks, so that really instead of dealing with one obstruction they were dealing with many. This could well be seen when an attempt was made to empty the bowel, it was easy to empty one loop, difficult or impossible to empty the whole. If an enterostomy were done, unless by some fortunate chance the bowel recovered, it would not drain. He did not believe that a case which had reached this stage would stand the manipulations required to empty the whole bowel. The probability was that after the bowel was emptied the kinking and distension would recur, and this was the terminal condition of ileus, whether due to a mechanical obstruction or a spreading peritonitis.

At the conclusion of the discussion Dr GREGORY EDE of New York showed cinematograph films of the stomach, and described the various normal types and the abnormalities from which it was possible to diagnose disease.

INTestinal Obstruction on Shipboard

The following case may be of interest as illustrating a possible danger in employing persons who have had laparotomies on long voyages where no surgeon is carried.

During the last voyage of this ship a man, aged 29, who was employed in trimming coal reported to the ship surgeon suffering from constipation of five days' duration. His previous history showed that four years earlier he suffered from acute appendicitis and that his appendix had been removed. Two years ago he suffered from severe abdominal colic with constipation and vomiting of ten days' duration. He was anaesthetized with a view to operation, but no operation was performed as apparently his condition was so bad that fears were entertained as to his survival. After he recovered from the anaesthetic his bowels commenced to act and he had remained well since, taking liquid paraffin daily.

He was placed in the ship's hospital and a simple enema administered without result. The next day two turpentine enemata were administered without result. He commenced to vomit, and his pulse became more rapid. On the next day he had faecal vomiting, with a rapid pulse (104). The abdomen became distended and a diagnosis of intestinal obstruction from adhesions following appendicectomy was made. It was decided to operate, although weather conditions were unfavourable, as the patient was steadily becoming worse. An anaesthetic was administered and an incision made through the right rectus muscle. The obstruction was found to be due to adhesions binding the caecum to the site of the incision of the previous laparotomy. The adhesions were freed and a band was found the thickness of a little finger binding the caecum down. This was tied and severed and the caecum became free. The omentum was drawn down and fixed over the previous scar and the abdomen closed. The patient was making an uneventful recovery when the ship reached port.

My thanks are due to Dr Hummel, medical superintendent, Canadian Steamship Company, for permission to publish this case.

OPERATION FOR EXTRAUTERINE GESTATION

In view of the case of extrauterine gestation mentioned in the report of Professor Kynoch's paper (*BRITISH MEDICAL JOURNAL*, July 4th, 1925, p. 15) the following may prove of interest.

A married woman, aged 33, was admitted to the Cumberland Infirmary on June 15th, 1925, complaining of severe spasmodic pains across the lower abdomen of two days' duration. She had had seven children, of whom only one survived. The others were still born or died soon after birth. She had had several miscarriages. In 1923 she was operated on for ruptured ectopic gestation and the right tube was removed. Since then her periods had been fairly regular until Christmas, 1924, when they ceased. In March, 1925, she reported at the hospital complaining of abdominal swelling and a history of three months' amenorrhoea. She wished to know if she were pregnant. The uterus was felt to be normal in size, but was pushed over to the right by a swelling, which seemed cystic occupying almost the whole of the pelvis. She was told to report again in a month.

When next seen, on June 15th, she was admitted to hospital. She had a large abdominal tumour extending up to the umbilicus. On palpation the abdomen was tender in both iliac fossae, especially on the left, and the tumour was felt rather more to the left side of the median plane than to the right. On auscultation the uterine souffle was heard clearly in the left iliac fossa, it could not be heard on the right side. No foetal heart was heard and no movements seen or felt. The patient would not submit to abdominal section, but consented to examination under anaesthesia. A vaginal examination was made and a large tumour found to fill the pouch of Douglas. Its nature suggested a foetal head of which the posterior fontanelle could be felt. The cervix was pushed very far upwards and forwards almost out of reach of the examining finger. A large tumour was felt in the left iliac fossa and spreading across the middle line while a smaller tumour to the right was taken to be the uterus. A diagnosis of extrauterine pregnancy, or pregnancy complicated by a large ovarian cyst, was come to. The pulse was 104, respirations 24 and the temperature 97.2°.

The patient was free from pain for the next nine days, but a recurrence of abdominal pain on June 25th made her consent to an operation, which was performed on June 26th by Mr MacLaren.

A medial suprapubic incision was made. Blood was found in the peritoneal cavity and the left tube was greatly distended. The uterus was enlarged to just above the pubes and displaced to the right. The tube was opened, and the placenta, which was adherent to the upper and anterior wall of the sac, was removed with very little bleeding. A live male child was then removed from the sac. The head was very fixed in the pouch of Douglas and gave rise to a little trouble in taking it out. The walls of the sac were adherent to the pouch of Douglas and to the transversum colon. The adhesions separated easily from the latter but not from the former,

and the pouch of Douglas had to be picked. A small piece of the picking was removed and there was a serious discharge from the wound for about three weeks. It ultimately healed perfectly, and the patient is discharged from hospital on July 25th a month after the operation.

The baby weighed 3½ lb on removal from the abdomen but steadily lost weight and died on July 8th, having lived thirteen days. The child was well developed with the exception of a marked double pes carneo-vilgus.

ADRENALINE IN ANGIO-NEUROTIC CONDITIONS

As the utility of adrenaline in angio-neurotic conditions does not seem to be fully recognized I think the following case is worthy of record.

A woman aged 40 had partaken freely of partridge. About half an hour afterwards a very profuse urticarial eruption appeared on the chest and abdomen. Later it invaded the back and limbs. It continued for several hours then she was seized with a feeling as if she was going to burst. In consequence the patient who had retired to bed, jumped out and leaving her room endeavoured to go downstairs but immediately fell down in an unconscious state.

When seen at 3 o'clock in the morning she had recovered consciousness and declared that she felt nearly all right. A dose of castor oil and a mixture of bromide and valerian were ordered.

Three hours afterwards the eruption appeared again being characterized by wheals of great size. Later the hands became oedematous. This state of matters continued all day and at 7 p.m. the face also became oedematous the swelling becoming so large as to cause considerable alarm to the members of the family with whom she was living.

At 9 p.m. I administered a hypodermic injection of 10 minims of adrenaline. In half an hour the swelling began to subside and the patient felt much better. A dead sinking feeling which had troubled her all day having vanished. At 10.30 all the symptoms had disappeared. Apart from several slight transient attacks of urticaria no further trouble followed.

An interesting point in connexion with this case is that the patient has been subject to occasional attacks of asthma for the last six years.

JOHN R. KEITH, M.D.

COLLOSOL ARGENTUM IN THE TREATMENT OF SEPTICAEMIA FOLLOWING ABORTION

I think that the following case will be of general interest, since it illustrates the almost dramatic effect of collosol argentum on the course of a septicaemia which had been uninfluenced by treatment for fourteen days previously.

A married woman, aged 19, was admitted to the Victoria Hospital Workshop on August 13th 1925, and a diagnosis of inevitable abortion was quickly made. Severe infection was already present and the features of the case strongly suggested that criminal induction had been attempted. She was curried on admission by Mr. A. W. Kirkham and 10 ccm of anti-streptococcal serum was injected subcutaneously immediately afterwards. In spite of four hourly doses of 4 grains of quinine sulphate and occasional injections of serum the temperature showed no signs of settling. After about a week pain and tenderness over the uterus indicated progressive metritis and the question of peritoneal involvement began to cause some anxiety. Occasional retention of urine necessitated catheterization. The serum was obviously having no effect, and on August 27th Mr. Kirkham advised trying collosol argentum which he had previously found effective in a case of septicaemia following abortion. A gluteal injection of 10 ccm was given on August 28th and 10 ccm daily thereafter. Twenty-four hours after the

a Operation five days before. b anti streptococcal serum 10 ccm. c collosol argentum 10 ccm. d sleeping.

first injection there was a distinct improvement in the general condition of the patient and after the second injection the pulse respiration and temperature had become almost normal. After the third injection it was decided to discontinue its use as a decision which was justified by the subsequent appearance of the temperature chart (reproduced herewith). I think this chart bears out the remarkable efficiency of collosol argentum in a case on which so often drugs are interminably in spite of all therapeutic measures.

CONGENITAL OCCLUSION OF THE FIRST PART OF THE DUODENUM

Congenital occlusion of the duodenum is a very rare condition. Of 13 cases of congenital occlusion or stenosis of the intestines collected by Barnard from the records of the London Hospital not one was of the duodenum. At Booth Hall Infirmary, with over 500 beds for children and about 4,000 admissions yearly, there had not been one case in nine years.

On September 5th I admitted to the hospital a female infant 2 days old. It had been vomiting persistently since birth although given nothing more than a few sips of water. The bowels had not been moved. The doctor who sent it in diagnosed the case as congenital pyloric stenosis. It was a full-time baby and pregnancy and labour had been normal. The weight at

birth was 6½ lb. Both parents are young and healthy. There are two other children alive, well and normal. Upon examination the infant seemed healthy.

After admission the stomach and the rectum were washed out both washings contained material like meconium. Emesis however persisted, the vomit closely resembling meconium (unfortunately no specimen was saved). The vomiting required very little effort, and was not like the projectile vomiting of infantile pyloric stenosis.

The infant died next day. I made a post mortem examination and in the accompanying diagram I have tried to show what I found. The stomach was large and distended while the pylorus was normal. The first part of the duodenum was greatly distended almost to the size of the stomach and ended blindly. Indeed the appearance of the stomach together with the duodenum was very like that of hour glass stomach. The second part of the duodenum commenced blindly at the ampulla of Vater, this end of the gut being embedded in the head of the pancreas near the uncinate process. It was joined immediately by the common bile duct. The remainder of the intestinal tract was normal, but it is interesting to note that the appendix measured over 2½ in in length had very little mesentery (and that near the base) and was freely movable. The gall bladder was rather large and distended with bile though the bile ducts were patent in their whole length. The liver was slightly enlarged. No other abnormalities were found.

Infirmary, Manchester

TEMPORARY BLINDNESS AFTER CONCUSSION

A case recently in St. Mary's Hospital, Paddington, showed an interesting condition of cerebral concussion.

On September 16th a boy aged 9 years was admitted to the hospital with a history of having been kicked on the head by a horse. There was a cut on the right side of the forehead just above the eyebrow.

The child was completely conscious but totally blind not even having perception to bright light. The movements of the ocular muscles were normal. The pupils were equal and reacted briskly. Two hours later perception to light returned in another two hours he had perception of moving objects and by the next morning he was completely recovered.

Owing to the ocular muscles and the pupil reflexes being intact it can reasonably be said that the lesion lay behind the anterior corpora quadrigemina and the internal capsule. It seems natural to conclude that the injury was a localized cerebral concussion due to contusion violence affecting only the visual centres in the occipital lobe.

I am indebted to Mr. D. C. L. Fitzwilliams, F.R.C.S., for permission to report the details of the case.

South Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

SOUTH WALES AND MONMOUTHSHIRE BRANCH

A clinical meeting of the South Wales and Monmouthshire Branch was held at the Royal Infirmary, Cardiff, on November 19th, with the President, Dr R. J. COULTER, in the chair. The meeting proved to be one of the most successful yet held by the Branch, seventy members attending.

Mr T. E. HAMMOND read a paper on movable kidney, dealing with the fallacies of treatment by simple rib stitch. One of the most constant symptoms was vomiting, which might be caused by traction on the duodenum, torsion of the pedicle, Dietl's crisis, or obstruction of the ureter by kinking. Pyelograms were most instructive. A 20 per cent solution of sodium iodide was used. Skirgams were demonstrated, and showed the dilated pelvis and altered position of the kidney, and kinking of the ureter as it crossed the brim of the pelvis. Professor A. W. SHEEN, in discussing the paper, dealt with the development of the kidney and its surgical bearing.

Cases and Specimens

Mr J. W. GEARY GRANT showed two cases of tubular skin graft. The first was a youth who had received a severe comminuted fracture of the left foot in which the whole plantar skin surface of the foot had been removed. The second was a woman in whom a lamp bulb had destroyed the skin on the anterior aspect of the forearm, laying bare the tendons and muscles. A perfect functional result had been obtained. Mr Grant then gave a demonstration on cholecystitis mentioning first the anatomy of the gall bladder and ducts and Hartmann's pouch. Treatment in the past had been by medicinal and surgical means. Thirty to fifty per cent of cases of cholecystitis were he said, unassociated with gall stones, and in only a few cases was it possible to get a culture from the bile or mucous membrane of the gall bladder. The pathological changes as seen in the mucosa were mentioned. Skirgams were then shown. Importance was attached to the absence of the duodenal cap, and the marked five hours' delay. In the differential diagnosis pyloric obstruction and gastric or duodenal ulcer were to be considered. Histories of cases were quoted, in some of which gastric ulcer had been suspected, but operation showed a normal stomach, the disease being located in the gall bladder. In others appendix dyspepsia had been suggested. Mr Grant emphasized the value of an accurate history, obtained from the patient. There was often a history of flatulent dyspepsia, with itching or vomiting. He asked whether the underlying cause of certain cases of cholecystitis was a metabolic defect. The paper was illustrated with a series of beautiful coloured lantern slides, skirgams, and pathological specimens.

Dr T. G. FIELD EVANS showed a collection of interesting skirgams: (1) a case of os trigonum, (2) erythrotabes, (3) carcinoma of the oesophagus, (4) osteitis of the skull with sequestra, following frontal sinus disease, (5) hydatid cysts of the lungs, one of the cysts giving the appearance of an enlargement of the left side of the heart, (6) skirgram of an opaque meal, showing the large intestine and partly filled appendix.

Dr A. MASOV JONES demonstrated a case of lateral sinus disease following mastoid suppuration. There had been pain in the ear and over the mastoid bone, some vomiting, and marked vertigo with nystagmus. A complete left-sided hemiplegia was noticed, followed by pain and swelling in the left shoulder-joint. The mastoid was opened and found to contain cholesteatoma. The temperature remained elevated and the other symptoms persisted. The lateral sinus was then exposed and opened, and found to contain pus. The internal jugular vein was ligatured. There had been uninterrupted recovery, and the hemiplegia had largely disappeared. Dr Jones stressed the importance of examining the lateral sinus in all doubtful cases.

Dr H. A. HAIG demonstrated microscopic specimens obtained from recent necropsies: (1) Subacute military

tuberculosis, originating probably in the prostate, the liver, bladder, and kidney had been invaded, and a superadded acute cystitis had occurred. (2) Carcinoma of the oesophagus, the post mortem examination showed enlarged mediastinal glands and deposit of carcinomatous cells in the pancreas. (3) Melanotic sarcoma of the skin of the breast, with recurrence in the operation scar, amputation of the breast had been performed, but the pectoral glands and scar were again invaded. There had been only a very small deposit of melanum in the secondary growths. Dr Haig invited a discussion on these slides as to whether the nature of some of the cells would suggest carcinoma or sarcoma.

Dr G. I. FARMER showed a specimen of fibroid uterus with pregnancy. The history of the case was discussed, with differential diagnosis. There had been pain and vomiting, and an abdominal tumour was felt. Operation was performed. A twisted fibroid tumour was seen, on the surface of which a large vein had ruptured. Owing to the weak condition of the patient, due to excessive loss of blood, the only feasible procedure was hysterectomy.

Puerperal Infection

Dr E. W. MACEAN contributed some observations on puerperal infection. He began by quoting certain figures illustrating the prevalence of the most important single factor in the puerperal mortality of this and of other countries, and indicated that in the British Isles Wales was unfortunately very prominent in the mortality tables. Though disputed by some it was commonly believed that during the last twenty years there had been no substantial diminution in the number of deaths from puerperal sepsis. "It was the nature of this fell disease which, on occasion, wrought havoc in the palace and in the well equipped maternity hospital is dramatically as in the hovel and the crowded tenement? Much patient and, indeed, successful work had been achieved in regard to the bacteriology of the problem, particularly as to the role of the streptococcus. But it was possible that the seeming innocuousness of the streptococcus in one case and its virulence in another might be related not so much, if at all, to any essential difference in the attacking germ as to variation in the factors constituting resistance to infection. There was reason to believe that organized work directed to the elucidation of this aspect of the subject would result in more successful prophylaxis and treatment, and truly these were urgently needed. Reference was made to the recognized clinical types of puerperal sepsis, their prevention, and some modes of treatment. The problem of notification was dealt with in some detail, and an interesting discussion followed.

Dr E. CONSTON WILLIAMS (MOH Glamorgan) differentiated true sepsis from disease and accident, and contrasted conditions obtaining in towns with those in rural Wales. In Glamorgan about 82 per cent of births were attended by midwives, so that as far as the exogenous element was concerned it depended largely on the midwife's association with the case. There was urgent need for a midwifery service in rural parts, which might come under the local authority. In these statistics of puerperal mortality and puerperal sepsis, he said, one must always remember the proportion due to criminal interference.

BRIGHTON DIVISION

At a clinical meeting of the Brighton Division of the British Medical Association held at the Royal Alexandra Hospital for Children, Brighton, with Dr W. BROADBENT in the chair, members of the hospital staff showed an interesting series of cases.

Mr L. A. PARRY showed three cases: (1) A child who, when 3 days old, had profuse vaginal haemorrhage. Treatment with elvir calen chlorid stopped this in twenty-four hours, and there was no recurrence. He mentioned that the prognosis in haemorrhagic disease of the newborn was bad, 80 per cent of a large series of cases ending fatally, but in a series of 35 in which there was no other haemorrhage except the vaginal there was no fatal case. (2) A case of torticollis in a boy aged 9, the wry neck was the result of a sterno-mastoid haematoma at birth. There was distinct facial hemiatrophy. The general opinion of the meeting was that it was a suitable case for

operation, but as it was of so long duration it would be wiser to perform the open operation rather than the subcutaneous (3) A case of double undescended testis in a boy aged 12, the testis on one side being in the inguinal canal and on the other in the abdomen. Opinion was divided as to the advisability of operation. It was suggested, on the one hand, that to wait till puberty supervened, hoping that the descent of the testis would follow, was the proper course, on the other hand, immediate operation was advised as being likely to be of most benefit.

Dr W. BROADBENT showed (1) A case of acute endocarditis diagnosed at first as an acute abdomen on account of an infarct in the kidney. The boy had improved much by being put on the balcony to sleep in the open air. (2) Two cases of encephalitis lethargica, one of which started with much delirium, meningismus signs, and nystagmus. The other patient was brought on account of violent attacks of temper after an illness lasting three days, in which the mother reported that the child was constantly asleep. This child also had nystagmus.

Mr M. FITZMAURICE KELLY showed (1) A boy, aged 4, shown at a previous meeting (February, 1925) with extreme spasticity of the right leg, particularly of the calf muscles. Section of the grey sympathetic ram by Royle's method was performed on March 18th, the boy now walked with only a very slight limp, and the heel was well down. (2) A boy, aged 9, shown at a previous meeting (May, 1925) with severe spastic paraplegia. Stoffels' operation had been tried without benefit (November, 1925). Sympathetic ramisection was performed on the right side on June 17th, 1925, and on the left on July 22nd, 1925. The boy now walked well, with the feet several inches apart and the heels well down. (3) A child, aged 3½, with a right spastic hemiplegia affecting chiefly the right arm, the hand being practically useless. It was proposed to divide the grey ram in the neck, and to show the case again at a later date. (4) A child, aged 3, with a large fluid swelling under the left gluteus maximus. There was apparent shortening of the left leg. A skiagram was exhibited showing malformation of the lateral mass of the sacrum, and of the ilium, with absence of the sacro iliac joint and defective formation of the lateral mass of the fifth lumbar vertebra. The patient, who was regarded as a case of lateral meningocele, had recently developed a paralytic talipes varus of the right foot.

Dr FLORENCE M. EDMONDS showed a case of purpura hemorrhagica treated by atropine.

Mr J. R. GRIFFITH showed two patients with pneumococcal peritonitis who had recovered after operation and the use of Pane's serum, and also a case of depressed fracture of the skull in a baby, trephining had been performed.

Reports of Societies.

MYOMECTOMY

A MEETING of the North of England Obstetrical and Gynaecological Society was held at Manchester on October 16th, the President, Dr J. E. GEMMELL, was in the chair, and lectured in sympathetic terms to the recent death of Dr Harold Clifford, president of the society in 1922. Dr LEITH MURRAY (Liverpool) read a paper on myomectomy in the non-gravid uterus, embodying a report of sixty cases.

Dr Murray said that for several years he had made a practice in hysterectomy for fibroids of enucleating immediately after operation all the fibroids present and of studying this as a possible surgical procedure. Myomectomy in pregnancy and labour differed as regards indications and conduct, and he therefore limited the present paper to myomectomy in the non-pregnant. His sixty cases included every operation for fibroids by the abdominal route, with retention of the uterus where the fibroids were lying wholly or partly within the uterine wall, and where an enucleation from the substance of the uterus had been the essential part of the operation. All cases with complete peduncles or with twisted pedicles, and fibroids wholly within the broad ligament, had been excluded. The fibroids under consideration were "dug out" of the musculature of the uterus, and cases were only recorded where an appreciable wound of the uterus was made. Cases where small superficial fibroids were easily discovered at abdominal operation—as, for example, in association with a pedunculated fibroid causing symptoms, an apoplectic ovary or mild appendiceal disease allowing of conservative operation—had been rigidly excluded because there was no real involvement of the integrity of the uterine wall

as the result of the operation. He maintained that the term "myomectomy" was best considered as one involving a wound of the musculature of the uterus. Dr W. Cough had recently suggested that some conservative operations were more successful as surgical than as therapeutic triumphs, but Dr Murray held that the uterus, appreciably mutilated by the enucleation of multiple fibroids, had a power of recuperation and involution incredible to those who had not tested it. In a case of a multipara, married two years, he had removed twelve fibroids weighing 17 oz., varying in size from an egg to a marble, with two per-sized fibroid polyps within the cavity, the uterine wall was deeply penetrated through eight incisions, and the cavity of the uterus was opened to disclose the two small polyps. Yet sixteen and a half months later this woman delivered herself naturally and easily of a full-term child, weighing 7 lb.

Absolute contraindications for myomectomy were furnished by desperate anaemia, the woman being past the child-bearing age, unless the operation was very simple, a "big of nuts" uterus physically impossible to enucleate, and fibroids associated with serious tubal or ovarian disease. Dr Murray did not think that degenerated fibroids and those adherent to their capsules were unsuited for enucleation, nor that degeneration in any degree was a contraindication to myomectomy. More than once the preliminary incision into a fibroid had penetrated an area of liquefaction of red degeneration, and the fluid so released had escaped into the peritoneal cavity, yet in no case had this caused any trouble, nor had he had any real trouble with old grey "wash-leather" fibroids, even with areas of calcification. Infection of a fibroid was rare. He had only once met with unexpected suppuration in an intramural fibroid in a non-gravid woman, streptococcal pus was found in one fibroid alone of a mass removed by hysterectomy. If he met with such a complication in the course of an enucleation he would not hesitate to complete the operation, even when pus had escaped, provided that the whole of the supporting fibroid could be removed, and he would close the uterine and abdominal wounds with good expectation of an uninterrupted convalescence. He had had no experience of enucleation of infected fibroids. Infected fibroid polyps were in a different class, and were probably unsuited for abdominal myomectomy, a vaginal operation or an abdominal hysterectomy was necessary. The indications for myomectomy lay within the child-bearing age, provided that the anaemia was not too severe and the fibroids not so numerous or so situated that the operation was physically impossible or injudicious on account of inevitable shock. The operation was undoubtedly more tedious, more difficult, and somewhat more serious than hysterectomy, but he had found a marked willingness on the part of both married and unmarried women to submit to the conservative operation.

Bouvier's tunnel method was much less complicated than it appeared, and an attempt should be made to avoid peritoneal incisions. An anterior incision was ideal, but not always possible. An essential point before enucleation was to make a preliminary incision into each fibroid, particularly in the case of the larger ones, a thin zone of condensed musculature round a fibroid was easily mistaken for the periphery. Cutting deeply brought to view the true capsule, and the finger could then be directed to the right level. In no case had there been much haemorrhage during the operation. Each fibroid was separated mainly by the fingers, vascular bundles in the capsule were resistant, and could easily be brought so near the surface that forceps could be applied before they were severed. The cavity was closed in layers, a round-bodied needle with unchlorinized catgut being used, the suture was usually continuous, but occasionally a mattress. A Lembert suture was inserted into the superficial layer, the edges should appear white as the result of tension. Trimming of the edges was often necessary, but it was better to leave such excess of uterine wall as would give a reasonable degree of adaptability to the peritoneal edges. The shape of the conserved organ did not matter, for by three months at the latest the uterus would be smoothly rounded and

normal Myomectomy would never produce its best results if there were hesitation in opening the uterine cavity. He had never refrained from opening the cavity where there was any doubt whether the fibroids removed were the cause of the symptoms. The difficulty was greater with smaller fibroids than with the larger ones. With small fibroids, where the main symptom was bleeding, it was quite sound practice to extend an incision into the cavity and then explore with the finger, perhaps followed by the curette, especially towards the cornua.

Discussing alleged drawbacks to the operation of myomectomy, Dr Leith Murray said that subinvolution had never occurred in his series of cases. Recurrence of symptoms due to fibroids left behind had not so far caused any trouble, but as most of the patients had been operated on in the last five years he might yet have to admit such a complication. In Giles's experience recurrence was 10 per cent, with 3 per cent requiring operation. Bonney had stated that recurrence was very rare, and in any case Dr Murray believed that any seedlings left would be unlikely to interfere with physiological function. There had been no persistence of undue bleedings and no patient in his series, where an after-report was obtained, had had any real menstrual excess. He had been surprised at the rapid way in which patients operated on for haemorrhage had practically normal menstruation from the third period after operation. Myomectomy, in his opinion, was a shade more serious than hysterectomy in many cases. Without causing immediate anxiety there had been a mild degree of shock, lasting a few hours in two cases, and definitely associated with the difficulty of the operation. The main risk in his experience was intestinal obstruction from leakage of blood into the peritoneal cavity round the surface of the myomectomy wounds. It seemed to him a rational proceeding to remove an anterior incision from danger by a ventro suspension, which he had employed on several occasions. He was convinced that a uterus, though much mutilated, healed satisfactorily with a negligible risk of weakness in any future pregnancy. He believed that preservation of the uterus was worth striving for, apart from pregnancy, and the after-histories where no pregnancy resulted supported this view. As regards the possibility of pregnancy occurring after myomectomy, the majority of cases operated on were not in young women. The figures recorded by Schmid, Noble, and Giles gave a percentage varying between 10 and 40 in women who had a chance of conceiving.

Record of Cases

Age of Patients—Of the sixty cases operated on twenty seven were 34 or under and thirty three were 35 or over.

Number of Fibroids Removed—In each of twenty six cases only one fibroid had to be removed the largest number in one case was twenty three weighing 17 oz, and in another case eighteen weighing 21 lb 14 oz, were removed.

Condition of Fibroids Removed—Necrobiotic changes oedema, cystic degeneration and hyaline degeneration were encountered, and one fibroid contained areas of calcification.

Symptoms Leading to Operation—These were in thirty one cases haemorrhage or haemorrhage with pain in twenty one cases pain alone and in eight cases pain with pressure symptoms.

Previous Pregnancies—Nine of the thirty four married women had had previous children and four had had miscarriages.

Operation—All cases were abdominal. The endometrial cavity was unavoidably opened in twelve cases intentionally in eleven in practically every case where haemorrhage was the main symptom the endometrial cavity was opened or exposed to direct palpation. In seven cases the oedematous and engorged endometrium necessitated an abdominal curettage. Every effort was made to reduce the number of external incisions of the uterus. 207 fibroids were removed through 139 incisions an average of 1.5 fibroids per incision. However it was possible to remove eighteen fibroids through eight incisions in one case and ten fibroids through two incisions in another.

After Histories—Two patients showed moderate shock an hour or two after operation but were never seriously ill. In one case a slight excess of menstruation was present eighteen months after operation. In a second case an alteration of the periodicity occurred and in every other case the reply to a definite question about periods had been absolutely satisfactory. The first period after operation and sometimes the second or even the third, in cases undertaken for haemorrhage were at times rather excessive but the great majority of patients after the third period were able to report a satisfactory type of period which persisted.

Subsequent Pregnancies—None of the single women had since married but one who at the age of 32 had a large red fibroid incited thanked him for preserving her uterus as she was engaged to be married. Seven (20.6 per cent) of the thirty four married women had had nine children normally born at full term and two others had had miscarriages one as the result of a motor

collision in which her husband was killed. This made the total of pregnancies following operation 26.5 per cent. Six of the nine cases had not been previously pregnant, the ages of these ranged from 30 to 40 and 42, the last two seemed worthy of particular emphasis. In only one of these nine cases was the uterine cavity opened during operation. Three of the married women who had not become pregnant were 42, 43, and 48 respectively.

Dr Leith Murray concluded that myomectomy was less difficult and dangerous than was often supposed, that it was available in a large percentage of cases in women of child-bearing age with symptoms due to fibroids, and that in women of reasonable age it should always be considered in preference to hysterectomy. As evidence of his view in this respect, he noted that in 1922 his proportion of myomectomies to hysterectomies was 1 to 8, whereas in 1923, 1924, and 1925 up to the present it had been for each of these periods 1 to 3.3. These figures, for the purpose of comparison with other records, included eight myomectomies performed during pregnancy.

The President remarked that conservatism during the child-bearing period had to be considered, but often where the uterus presented a ragged appearance after myomectomy he had deemed it advisable to perform subtotal hysterectomy. Dr Murray's results, in freedom from haemorrhage and fatality, and the after-results of pregnancy and parturition at term, marked a very important advance. In 1897 the late Dr Alexander, at a meeting of the society, described six cases of abdominal myomectomy for fibroids varying in number from six to twenty-six, the operator left the uterus attached to the abdominal wall, the cavity packed with gauze, and thus treated extraperitoneally. The opinion was then expressed that myomectomy for multiple fibroids was not practicable. Technique had steadily improved, and reliance on the peritoneum had led to confidence in a successful issue. Dr Gemmell did not think that to miss seedling fibroids was a great error, as the patient might have had children before the necessity for further operative treatment arose.

Dr FLETCHER SHAW (Manchester) said that in a young woman who might reasonably expect to have further family myomectomy was the ideal operation, but where a woman had already had several children, and was aged 40 or more, he thought she should be allowed to choose between hysterectomy, with absolute certainty of no further trouble, or myomectomy, which preserved the uterus, but with a slight risk of recurrence of the original trouble. He had been impressed lately by the frequency with which he found a loop of intestine firmly adherent to the uterine serosa without there having been any clinical symptoms of this condition. He had previously reported to the society a case in which he had removed twenty-three fibroids from a uterus, a few years later that patient had become pregnant, and was delivered of a full-term child without any untoward symptoms.

Dr A. DONARD (Manchester) had removed a fibroid by myomectomy in 1890, using buried gut for the first time. He was not so favourably disposed towards myomectomy for two reasons: first, that many women did not want children, and secondly, the result of the operation was not so satisfactory as hysterectomy.

Professor BRIGGS (Liverpool) said that it was impossible to remove all the fibroids from the uterus on every occasion. He thought there was a considerable difference between the words "myomectomy" and "enucleation." In performing myomectomy he had always pretended "stabbing" the capsule finely to make it more evident in enucleating fibroids.

Mr W. W. KING (Sheffield) thought that the condition of the cervix ought to be considered, lest a potentially cancerous condition be left behind.

Dr W. FORDYCE (Edinburgh) had been deterred from myomectomies by the haemorrhage and shock that resulted. Cutting into the capsule of the fibroid he considered of great importance. In later life, or after the woman had had three or four children, the operation of hysterectomy, in his opinion, was preferable to myomectomy.

Dr LEITH MURRAY in his reply, suggested that the words "myomectomy" and "enucleation" were almost synonymous. He had encountered haemorrhage and shock on very few occasions, and only in one case had there been intestinal obstruction.

Malformation of Pelvic Organs

MI A GOURN (Leeds) read notes of a number of cases of malformation of the pelvic organs which he had encountered

1 *Atresia of Vagina with Menstrues retained up to the Age of 26 Years*—At the age of 15 this patient had pelvic pain frequently at intervals of a month from then there had been no discomfort till just before admission to hospital. She had been aware that the lower part of the abdomen was enlarging but she attributed this to fat. She had been married five years, but no steps had been taken to remove the obstruction. A few days before admission a black vaginal discharge had been noticed. On admission the temperature was 99° and pulse 120. Examination of the abdomen showed a medium swelling the size and shape of six months pregnancy, tense and fluctuant and rather tender. The external genitalia were small, but otherwise normal. The remains of the hymen were seen, and a finger passed beyond this for $\frac{1}{2}$ in, and was then checked by a transverse septum. The black, tarry fluid was found when the patient was anaesthetized to exude from a pinhole aperture in the transverse septum. The septum was dissected away and three to four pints of black, grumous fluid flowed out with a small characteristic of *B. coli* infection and gas escaped with it. The cavity was irrigated with lysol lotion. It was concluded that both uterus and vagina had been distended, but there had been no distension of the Fallopian tubes. The temperature fell three days after operation. Later the patient menstruated three times in a perfectly normal manner and then became pregnant. This case was noteworthy because the condition had persisted so long with trivial symptoms and without treatment until spontaneous leakage and infection occurred, and also because the uterus resumed its functions so soon.

2 *Absence of Uterus and Vagina*—This patient aged 25 sought advice because she had never menstruated. She had the general appearance of a well developed young woman with normal secondary sexual characters. Abdominal examination showed nothing unusual. The vulva and hymen were normal, but a finger was arrested an inch above the fourchette. Combined rectal and abdominal examination showed no trace of the uterus or upper part of the vagina. She was told that she was the subject of a deficiency which would in no way affect her health but would render pregnancy impossible. She was advised not to think of marriage but to be content in the exercise of her profession that of a nurse.

3 A similar absence was found in a woman, aged 22 and engaged to be married. The state of affairs was explained to her mother and the opinion given that marriage should not take place because of the grave risk of unhappiness.

4 *Uterus Didelphys with Vaginal Abnormality*—This woman, aged 27, had had one pregnancy three years previously which ended prematurely the child being stillborn. On examination the upper part of the vagina was unusually wide from side to side and a cervix felt on each side, the left one was normal but on the right side a membrane with a small aperture covered the cervix which could just be felt. Under an anaesthetic the membrane was freely incised. An exactly similar malformation had recently been described by Wiart and Surru. They very aptly compared this membrane to a perineum covering its glands.

5 *Unicorneate Uterus with Absence of the Appendages of the Left Side*—This patient on examination appeared to have a retroverted uterus deviated markedly to the right side with irregular masses on either side taken to be the uterine appendages. An operation was advised for chronic salpingitis and a large number of adhesions were separated, showing the uterus lying on the right side. It was small and conical and the right tube and ovary were badly disorganized by inflammatory disease. The left cornu of the uterus with its appendages and the left broad ligament were completely absent. The round ligament ran towards the cervix. In the left side of the pelvis an ovoid mass thought to be a cyst or disced ovary, after exposure was recognized to be the left kidney.

6 *Double Ureter discovered in the course of a Vaginal Operation*—In dissecting the structures on the left wall of the pelvis two separate ureters were found lying parallel and a quarter of an inch apart they united about 2 inches before entering the bladder. In this patient this abnormality could hardly be missed but in a patient with much extraperitoneal fat it might be. Double ureter was one of the commoner anatomical variations and ought to be remembered. After the ureter had been found the surgeon proceeded more boldly and was apt to disregard any other structure encountered so long as it did not bleed so an extravasation of urine might result.

Dr A. DOWD (Manchester) referred to a case of his wherein there was a pelvic kidney, and the organ was left in situ at operation (subtotal hysterectomy). Symptoms of a low toxic type developed within a few days, later followed by a fatal result.

Dr LEITH MURRAY (Liverpool) reported two cases of uteruloplasty for uterus bicornis unicollis (symmetrical) followed by repeated pregnancies. These cases showed the non-gravid uterus as an organ capable of maintaining its integrity during child bearing after a complete hemisection of the corpus, and confirmed Munro Kerr's and Bonney's experience of the same operation.

1 A nullipara aged 25 married six years came complaining of severe haemorrhage and a swelling of the uterus was diagnosed

as a fibroid. At the operation in 1919 a bicornuate uterus (uterus bicornis unicollis symmetrical) with normal appendages was found. A mesial wedge was removed and the two uterine flaps stitched together with catgut, without much difficulty produced a very normally shaped organ. The endometrial gutter on each side was curetted before closure she was delivered in 1922 at the thirty-fourth week of pregnancy of a baby weighing 4 lb 9 oz which was still alive. A second child was stillborn at the thirty-third week as the result of placenta praevia. A third pregnancy resulted in the delivery at full term of a child weighing 6 lb 4 oz.

2 A woman aged 34, married eleven years had had two children the second five years previously, she complained of haemorrhage pain in the back and left side. At the operation a bicornuate uterus was found, bound down by an adhesion to the pouch of Douglas. Uteruloplasty followed by ventro-suspension was performed in October, 1920 and in December 1921 the patient was delivered of a full term living child weighing 9 lb, spontaneously. A second natural delivery took place on September 3rd 1923.

TREATMENT OF BRONCHITIS IN CHILDREN

At a meeting of the Manchester Medical Society held on November 4th, with the President, Professor A. H. BURGESS, in the chair, Dr JOHN F. WARD read a paper on the treatment of bronchitis in childhood.

Dr Ward began by insisting that the successful treatment of bronchitis could only be expected when recognition of the morbid changes in the bronchial tubes was correlated with knowledge of the action of the remedies employed. In the later stages of acute bronchitis and in chronic bronchitis excessive secretion occurred in the bronchial tubes, this might cause blocking of the tubes, with consequent collapse of the corresponding portion of the lung, and a spread of infection into the alveoli. Some degree of toxæmia resulted from absorption in all cases. Efficient coughing was the only way in which the tubes could be cleared. Coughing was dependent upon two factors—reflex and muscular action. Where there was much toxæmia the reflex excitability was diminished, and also the muscles quickly became atonic, especially in children. The general method adopted to clear the tubes was the use of expectorants, their action was entirely reflex, increase of secretion in the tubes being caused but no increased power of expulsion. They all acted by irritating the gastric mucosa, and in large doses were emetics. This irritation in itself was objectionable in young children, but most cough mixtures must be inert because of the high degree of dilution, and the addition of sedatives, such as tincture of opium, which counteracted the reflex action. If these drugs did not increase the secretion but merely rendered it less viscid and easier to dislodge then use would be logical, but there were better ways of relieving this end. The three principles of treatment were to seek for and remove the cause, to increase resistance of the patient, and to relieve symptoms which needed relief. The cause of bronchitis in children as in adults, was bacterial invasion, but it was always secondary, and in a very large proportion of cases it was often secondary to unhealthy conditions of the naso-pharynx, which might be present at a very early age. In other cases the cause was to be found in a rachitic constitution which rendered the child particularly susceptible to attack of both the respiratory and gastro-intestinal tracts, and also considerably weakened the power of the cough by causing marked muscular atony. Many cases of this kind were without bony deformities. Animals experimentally fed on foods deficient in fat-soluble A were particularly liable to death from respiratory disease. Lack of exposure to sunlight was also a potent factor, and was probably more important than damp in causing the greater frequency of bronchitis in winter as compared with the summer. To increase the resistance of the patient vaccine therapy was logical especially in chronic cases, but it was difficult to obtain autogenous vaccines in children, and the results were not very satisfactory. Better results followed dietetic treatment, with abundance of fresh air and sunlight. Artificial sunlight was beneficial in bronchitis as in rickets and malnutrition, and cod-liver oil was of great value. The chief symptom calling for relief was cough but this was not always to be checked, it might serve a useful purpose, and might then be assisted by inhalations of steam, hot drinks, all this, or small doses of potassium iodide, to make the secretion less viscid. When the tubes were dry and the cough was

irritating and exhausting the diagnosis of bronchitis should be revised. A possible cause was irritation of the pharynx, and relief was then obtained by demulcents, the cause might be at a greater distance—as, for instance, otitis media or even irritation of the chest wall. Steam was very useful for relief of cough with dry tubes, also small doses of chloral, opium was always dangerous in young children, and belladonna was chiefly useful in cases associated with spasm. In the treatment of chronic bronchitis attempts might be made to disinfect the tubes by inhalations. Drugs given by mouth as antiseptics must be much too weak to be effective when excreted, if they ever were, by the bronchial mucosa. The cause of chronicity should be sought and treated, and the general condition of the child be improved by diet and sunlight. Small septic tonsils might be the cause of chronic infection of bronchial tubes they were just as important in this respect as large tonsils.

Myocardial Disease

Dr J C BRIMWELL, in a paper on recent advances in the diagnosis and prognosis of myocardial disease, said that he would confine his attention to a single group of clinical cases in which the electro-cardiogram was helpful both in diagnosis and in prognosis. The accurate quantitative estimation of myocardial damage was often difficult, especially when it had to be based almost entirely on subjective symptoms. In such circumstances any additional objective evidence obtained by special methods of examination was of considerable value. The particular group of cases to which he wished to refer were those in which the electro-cardiogram showed the condition of "bundle branch block." Willis had brought forward evidence that in angina pectoris, other things being equal, certain abnormalities of the ventricular complex added to the gravity of the prognosis. Oppenheimer and Rothchild had shown that certain abnormalities of the electro-cardiogram were frequently associated with coronary arterial disease. Cowan and Brimwell had recently studied a series of 24 patients with bundle branch block, of these 15 had died within eighteen months of the recognition of the lesion. The remaining 9 patients were still living, 4 of them now having been under observation for more than three years. There appeared, therefore, to be a small subgroup of cases exhibiting bundle branch block in which the prognosis was not unfavourable. These were probably cases in which the lesion causing the block was localized and stationary. Clinically these cases did not manifest signs of encephalopathy, and they served to illustrate the importance of correlating the electro-cardiogram with the clinical findings. A persistent electro-cardiogram of bundle branch block afforded definite objective evidence of a myocardial lesion, and was therefore of considerable value in diagnosis. The prognosis in such cases depended on whether the lesion causing the block was stationary or progressive.

STAPHYLOCOCCAL HAEMOLYSIS

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland held on October 30th, the President, Professor JOSEPH W BIGGER, read a paper on staphylococcal haemolysis. Professor Bigger explained that his communication was merely preliminary, since the research was by no means complete. He first drew attention to the different appearances found in blood-agar plates as the result of the growth of different strains of *Staphylococcus aureus*. With some strains no change occurred, with others good haemolytic zones were produced, while a third type gave chiefly a brownish discoloration. By means of the technique of "layered" plates it was found that haemolysis occurred first then the liberated haemoglobin diffused through the medium and finally it became altered by the action of acid and oxygen. Professor Bigger dealt next with the production of lysis in broth cultures. This lysis had no action on human cells, but acted strongly in sheep cells. It was readily produced, and in broth of pH 7.2 reached its maximum in about seven days falling subsequently, it appeared more rapidly in an acid, and

more slowly in an alkaline medium. The action of heat, filtration, and dialysis on this lysis was then considered. An interesting point was that, with many lytic broths, heat followed by cold produced better lysis than either heat or cold alone. Lastly, the method used for producing a lysis acting on human cells was described. As the methods of its production and many of its properties were different from that acting on sheep cells, Professor Bigger thought that the two lysins were quite distinct.

Dr W D O'KELLY said that the work done had opened up a large field for research, which would obviously take some years to explore. Professor J T WYCHERLEY remarked that although this research had no apparent utilitarian aims, yet such work was often followed by useful discoveries. He deplored the fact that recent books copied earlier ones without experimental verification of the statements contained in them. In this way mistakes had been handed down from one writer to another. The fact that the lysins acting on human and sheep cells were essentially different interested him very much, and he suggested that by this means the bloods of various animals might be distinguished.

Mesothelioma

Dr J D CANNON, who with Dr W D O'KELLY exhibited an abdominal tumour (mesothelioma) removed from a child 3 years of age, said that this large abdominal tumour was situated in the right upper abdomen. It passed under the ribs above, extended beyond the mid-line towards the left, and descended to a few fingerbreadths below the umbilicus. When the abdomen was opened a large growth was discovered growing high up in the mesentery of the small intestine. The tumour was successfully enucleated. Dr O'KELLY added that this was a solid tumour and measured 6 inches in diameter, it was of the nature of a terato-blastoma, and was highly malignant. From the anatomical situation and the nature of the growth, it was probably a remnant of the Wolffian body.

OPERATIVE TREATMENT OF EXOPHTHALMIC GOITRE

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, held on November 6th, the President, Mr R C B MURPHY, in the chair, Mr R A STONEY showed a woman of 30 who had been much benefited by surgical treatment for exophthalmic goitre. Mr Stoney said that in spite of rest in bed, sedatives, and the administration of Lugol's solution, the pulse rate, which at first fell, increased and the patient lost weight. Just before her operation the basal metabolism was increased by 46 per cent. The patient was given rectal ether, and the right lobe, isthmus, and lower half of the left lobe were removed. Now, three weeks after the operation, the basal metabolism had fallen to 27 per cent below normal, and the pulse had become slower and was steady. Tremors had almost disappeared, exophthalmos had decreased, the weight had increased, and the patient stated that she felt much better, and was now eating and sleeping well. Mr H STOKES said that he had operated on many cases of patients with exophthalmic goitre, and the results on the whole had been distinctly good. He had found that iodine acted very well, he had recently treated a patient with iodine and her pulse rate had come down, but immediately he stopped the iodine her pulse quickened again. He did not perform a lobectomy, but he removed a large portion of the centre of each lobe, after ligaturing the upper lobe. He had had about four or five such operations each year for the last few years. The incision employed by Mr Stoney gave very good access to the lobe, and in lobectomy it was necessary, but Mr Stokes thought that otherwise the operation he himself did was much easier. He had operated on about thirty-five patients. Of these two had died, one a very bad case, never recovered from the anaesthetic, and the other died from septic pneumonia. Dr G E NESBITT said it was sometimes stated that phlebotomy was reluctant to let their patients be operated upon. With this he could not agree, but they wanted more

proof that operation was the best method of dealing with these cases. He thought that most people with exophthalmic goitre would prefer to be treated by x-rays first, than to have an operation performed. Good results certainly were often obtained by x-ray treatment.

Mr H MEADE believed that surgeons seldom received patients with exophthalmic goitre early enough, if good results were to be obtained by operation. It was necessary to operate early. He had had two deaths, but one patient had a toxic goitre. He always used a transverse incision, and except in exophthalmic cases he did not cut the muscles.

Mr L G GUNN divided cases of goitre into two classes—the mild and the very severe cases. He had operated on fourteen severe cases, and two had died directly as a result of the operation. Of the other twelve, two had shown a definite return of exophthalmic symptoms—one after five years, the other after eight years. He had probably not taken a sufficient amount of thyroid gland away, but he felt that even after operation there was likely to be a certain amount of recurrence. Much depended on the patient. If a patient had only to do light work, or no work at all, then medical treatment and x-rays might be employed, but if the patient had to do hard work, then he would advise operation. He had seen many cases greatly improved after medical treatment, but very few of these patients had been fit to go back fairly soon to work, while after operation they were able to work in quite a short time. A simple operation was sometimes followed by a very severe reaction, and even death.

Mr STONEY, in reply, said that he had never operated on a patient with exophthalmic goitre who had had treatment by x-rays, but he had operated on a case of ordinary goitre, and he looked on it as one of the most difficult operations to perform. The thyroid had become hardened, and it was necessary to cut it out by dissection from the tissues of the neck with continuous bleeding all the time.

Multiple Myomata

Mr H MEADE showed a case of multiple myomata in a male.

He first operated on the patient in 1920, removing what appeared to be a scellaceous cyst in the thigh, but the pathological report showed it to be a myoma. On further examination it was discovered that the patient had four others in different parts of the body which he subsequently removed. The patient returned in 1924 with recurrences in other parts of the body, one in the liver nearly 6 inches in diameter and one in each leg which were causing him a good deal of pain. Owing to the widespread nature of the trouble Mr Meade decided not to operate, and for the same reason Dr Hayes thought deep x-ray treatment inadvisable. The patient returned again in July, 1925 requesting the removal of the tumours in his side and legs which were causing him much pain and prevented sleep. The tumours had only increased slightly in size and the general condition of the patient had not deteriorated. Mr Meade decided to operate. He removed one tumour from the calf of each leg in which the nerves were involved one from each side of the neck, two from the side of the thorax one from the side of the left arm, one from the right forearm, and one from the right buttock, but he did not remove the tumour in the abdomen or a small one in the back. Complete relief from pain followed.

Mr Meade showed the patient, who now had two further growths—one in the left arm and one in the front of the left thigh. The growth in the liver had increased perceptibly in size, being now between 10 and 11 inches. The histological report from Dr T T O'Farrell was to the following effect:

Sections taken from the largest tumour were composed mainly of spindle-shaped cells arranged in bundles some cut transversely and others longitudinally. The cell nuclei were more or less rod-shaped, and in transverse section appeared as small dots in the centre of the cells. The cells were like those of leiomyoma. Scattered through the tissues were two other types of cells—one a round cell containing a fairly large mitotic nucleus and the other fairly numerous giant cells. The giant cells varied in size and contained from one to several nuclei. In places the nuclei appeared to fill the cell. No striations were found in the protoplasm of the giant cells and they bore otherwise no resemblance to striped muscle fibres. The blood vessels on the whole were scanty, and van Gieson's stain revealed very little fibrous tissue. Sections taken from a smaller tumour exhibited many of the characters of the first specimen, but there were no cells containing mitotic figures and giant cells were scanty. The first specimen showed undoubted malignant change, but without further investigation it was uncertain whether it was myoma malignum or spindle-celled sarcoma of unusual type.

MEDICO-LEGAL SOCIETY

At a meeting of the Medico-Legal Society, held in London on November 17th, with Sir WILLIAM COLLINGS in the chair, Sir BERNARD SPILSBURY read a paper by Dr JOSEPH J. LEVIN, of the General Hospital, Johannesburg, Lecturer in Forensic Medicine to the University of Witwatersrand, upon a case of accidental wounding.

A South African Shooting Case

It appeared that while a man was extracting cartridges from a revolver, a cartridge exploded and the bullet entered the body of his wife, who was pregnant, passing through the foetus. The wife had stated that the child was alive that morning, but the next day it was delivered stillborn and the wife herself died three days after the accident. Dr Levin made a necropsy, and concluded that death had resulted from inflammation of the kidneys, upon which the coroner's court found a verdict of "Death from natural causes." The court did not find that the bullet wound accelerated death, but if there had been such finding, could the husband have been charged with murder? The child died as a result of injuries produced by the bullet, but could a child which had never breathed have been murdered? Further, could the husband have been charged with procuring abortion? Dr Levin discussed the South African legal authorities on the law of murder, and said, as the facts precluded any intention to kill, no charge of murder would lie. The coroner had found there was no culpable negligence on the part of the husband, and, in view of the medical evidence, it could not be argued that the act of the husband either caused or accelerated the death of his wife. A charge of intent to do grievous bodily harm, or even of common assault, could not lie in the circumstances. Then, as to "murder" of the foetus. South African law appeared to follow English law in requiring that the child must be "born alive," must have "completely proceeded in a living state from the body of its mother, whether in a case of suspended respiration it has breathed or not, and whether it has had an independent circulation or not, and whether the navel string is severed or not." This was a quotation from the Code of 1886, but it would be inadvisable to accept it as a final statement of South African law, as a case in the South African High Court in 1895 decided that the killing of a foetus was infanticide. The South African Criminal Procedure Code of 1917, however, laid down "On the trial of a person charged with murder or culpable homicide of a newly born child, such child shall be deemed to have been born alive if it is proved to have breathed, whether or not it has had an independent circulation, and it shall not be necessary to prove that such child was at the time of its birth entirely separated from the body of its mother." It was, however, in the discretion of the judge to impose a sentence other than death upon a conviction, and it was hardly likely, save in cases of great inhumanity or atrocity, that a sentence of death would be passed. Where the child was not born alive naturally the question of another crime, that of procuring abortion, might arise, but there could be no such question in this case. The husband, then, was guilty of no crime.

Sir BERNARD SPILSBURY, opening the discussion, said though the death of the woman was not the direct result of the injury, it might be that the injury to the child, by causing its death, accelerated the death of the mother. From the post-mortem examination it was, in his opinion, evident that the woman was in grave danger before the accident of developing puerperal eclampsia, and, as the mortality from that condition was a heavy one, the woman may have died in any event somewhat later in pregnancy. It would not be right therefore, to state that apart from the injury to the woman's life was in no danger. He had no doubt, however, that the injury, by precipitating labour, accelerated death.

At the close of the discussion in which several members took part Sir BERNARD SPILSBURY read a further paper on bullet wounds in their medico-legal aspect, in the course of which he referred to interesting cases where the markings produced on the body and clothing by the discharge of firearms at close range were of great value in deciding in what manner the wounds had been caused.

Reviews.

THE PRACTICAL
MEDICAL JOURNAL

GENETICS AND EUGENICS
Dr C C HURST has collected into a single volume, *Experiments in Genetics*, the more important papers reporting the result of his researches in the genetics of plants, animals, and man, carried out during a period of thirty years (1894 to 1924). The first four papers record experiments in the hybridization of orchids undertaken before the Mendelian classification of orchids. The following twenty papers report the results of Mendelian experiments with various genera of plants and animals, together with Mendelian researches in the horse and in man. These constitute an experimental demonstration of the Mendelian principles of heredity. The remaining papers deal mainly with the problem of the application of the principle of Mendelism and the breeding of plants and animals, and to some extent with the question of eugenics in man.

It would be impossible to find a more masterly presentation of the principle of Mendelism than is contained in this volume, conveyed in exceptionally pure and pleasant English. Naturally much of the work is outside the immediate sphere of medical interest, being of a purely technical character bearing on the Mendelian principle. But the author's observations on the relation of genetics to eugenics deserve the careful attention of those who are, perhaps, unduly enthusiastic in their efforts to introduce the latter into the outward appearance of the individual. Neither the author states, "nor a knowledge of its necessity is a safe guide to its breeding potentialities. The time mesuring of heredity is neither the somatic character of the individual nor of his ancestors, but its gametic constitution, and, in our present state of knowledge, this can only be determined by experimental breeding on Mendelian lines." Again, "in studying the inheritance of the more simple physical characters in man, it is evident that we are as yet only feeling our way towards the solution of certain larger and more complicated problems which are of vital importance to the human race. The future of eugenics depends very much on the solution of those problems. I do not wish for one moment to suggest that the art of eugenics has been born before its time, but I do feel that before we can venture to apply the scientific principles of genetics to human life we must first make our foundations sure. For this reason I am convinced that a good deal of sporadic work in human genetics will have to be done before any considerable amount of practical good can be accomplished in eugenics. Eugenics is simply applied genetics and sound eugenics can only be founded on sound genetics."

PIORRHOIA AND APICAL ABSCESS

The volume entitled *Teeth and Jaws Roentgenologically Considered*, by Dr HERMAN A. OSGOOD, is the fifth of a series of x-ray atlases projected and edited by Dr James T. Case, late president of the American Roentgen Ray Society. The object is to supply a diagnostic guide rich in the fruit of experience of leading authorities in special fields of post-graduate course from the very men whom he would seek in personal visit, and to leave him with an invaluable series of master roentgenograms which he may study and with which he may make comparisons as often as desired. The volume begins with a summary of the normal, pathological and artefact conditions which may be met with in the author expresses his views on two burning questions of dental pathology—the differentiation of apical abscess from chronic apical abscess and the nature of first point when he writes: "Where there is a small abscess without erosion of the root tips, the x-ray evidence shows that the average case clears up entirely where the canal is cleaned out and filled." This is just

Experiments in Genetics. By Charles Chamberlain Hurst. Ph.D. Cantab. 148 pp. Cambridge. The University Press. 1925. (Cr 4to pp xviii + 578. 14 figures + 1 map. 50s. net.)
Teeth and Jaws Roentgenologically Considered. By Herman A. Osgood. 148 pp. New York. P. B. Hoeber, Inc. 1925. (8 x 10, pp xviii + 293. 407 figures. 72 plates. 10 dollars net.)

what we should like to believe, but the author gives no x-ray pictures to support his statement. With the help of the x-rays he considers that three distinct types of piorrhoea can be distinguished: a form due primarily to local irritation, a form in which there is alveolar recession without pocket formation, and a form primarily of systemic origin, in which there is alveolar recession of systemic origin with or without pocket formation. This last is the "piorrhoea." However much truth there may be in this classification, we have to confess we do not see in the x-ray pictures any unequivocal proof of it. All the appearances can be equally well explained as the result of local sepsis. It is interesting to note that this observation applies with equal force to the illustrations given of "periapical abscess"—the so-called traumatic occlusion. The volume itself consists of 407 x-ray figures illustrating well the normal, abnormal, and artefact appearances of the teeth and jaws. The figures are printed in negatives for convenience of comparison with everyday work, and to make more clear the details of the finer structures around the tooth apices most of them have been enlarged two and a half times. These figures are of a high quality, and well repay the work that both author and printer must have expended on them. The most interesting one, perhaps, those showing "sepi bone," especially one showing thickening of the edge of the mental foramen from a case of persistent neuralgia, and in "artefact" in which over penetration has blotted out all the interdental bone in the centre of the film, leading to a mistaken diagnosis of advanced piorrhoea. A volume such as that before us should be a most valuable object lesson of the dangers of dental sepsis.

PHYSIOLOGY, NORMAL AND PATHOLOGICAL

The second volume, which deals with respiration, is the first portion to appear of a handbook of normal and pathological physiology, which is being edited by Professor A. BETHE, G. V. BERGMANN, G. EMMERICH, and A. ELLINGER. There are no fewer than 315 contributors, and the whole work, it is stated, will consist of 21 volumes, each summarily of the same size as the volume under review, which contains 552 pages.

The editors, in their general preface, explain that it is fifteen years since the last volume of Engel's handbook of human physiology appeared, and that in their view the time is ripe for a new encyclopaedia of this science. The scope of the present book is, however, more extensive than was that of any of its predecessors, for it includes not only the whole of normal physiology, but also pathological physiology and pharmacology, and, besides dealing with vertebrate physiology, treats also of invertebrate and plant physiology.

The book will therefore deal with most of the functional manifestations of which living tissues are capable, and may be considered as a handbook of biology, using that term in its widest sense. The contributors include the majority of the physiologists of Central Europe, together with a certain number of writers from Holland, Switzerland, Sweden, England, and America. The completed handbook, together with Abderhalden's handbook of biological methods, which is planned on a similar if not larger scale will comprise a fair-sized library. We must recognize, however, that these encyclopaedias have become so vast that no one can keep touch with it, even if it happens to be available.

The volume under review contains fifteen chapters by fourteen different authors, and the titles of the chief chapters give a good indication of the field covered. The subjects dealt with are: anatomy of the respiratory apparatus, the physiology of respiratory movements, the physiology of the respiratory tract, the chemistry of the exchange in the lungs, the regulation of respiration, the pathology of the respiratory tract and of respiration, the pharmacology of respiration, gas poisoning, dust inhalation, and respiration in plants. All the articles

Handbuch der normalen und pathologischen Physiologie. Band II. Atem- und Gasaustausch. Herausgegeben von A. Bethe, G. Bergmann, G. Emmersch und A. Ellinger. Berlin: Julius Springer. 1925. (Sup. 8vo. 8to. pp. xv + 552. 122 figs. 39 gold marks. bound 44.40 gold marks.)

give good summaries of the present state of knowledge in the subject dealt with and give full references to the recent literature

The inclusion of chapters on pathological physiology is especially to be welcomed, since this plan will help those who wish to learn the exact significance in disease of the laws established for normal respiration

TISSUE CULTURE

DR ALBERT FISCHER's book *Tissue Culture*⁴ is an important addition to the literature of the subject. Dr Fischer succeeded in obtaining the first permanent strain of epithelial cells in pure culture, and has published several other articles on tissue culture to which reference is made in the text. But the book is by no means limited to an account of the author's own researches, though naturally the problems at which he has worked himself have greatest interest for him, and to these he frequently returns.

The book begins with an historical review of the subject, which is followed by chapters on culture media and on methods of tissue cultivation. In these the author distinguishes between mere survival of tissue cells and actual growth. The fifth chapter, on pure strains of tissue cells, describes methods of obtaining pure cultures of fibroblasts, epithelial cells, cartilage cells, and lymphocytes, and contains a great deal of practical detail which laboratory workers in this field will find specially useful. To the general reader the last two chapters will make the strongest appeal, for here the author touches on many fundamental problems of biology on which tissue culture work is beginning to throw new light, and raises many other questions which in the future this new branch of biology may help to answer. The book is well illustrated and contains a fairly comprehensive bibliography.

FOOD IN INFANCY AND CHILDHOOD

THESE two volumes, the second and third, of the second edition of CZERNY and KELLER's *Des Kindes Ernährung, Ernährungsstörungen und Ernährungstherapie*,⁵ proceed methodically with their appointed task. A notice of the first volume, with an indication of the scope of the whole work, was published nearly two years ago (December 15th, 1923, p. 1163).

The second volume completes the account of nutrition (including food, digestion, and metabolism) in the healthy infant and child. It deals with food requirements, especially in infants, and with various formulae for determining them, with growth in weight and length up to and beyond puberty, as determined by many statistical investigations, gives an imposing mass of metabolic data, and concludes with a chapter on weakly children.

The third volume begins the attack on the large subject of nutritional disorders in the infant and child. In this matter the authors are deeply and personally interested, for they have themselves introduced a new classification of the dyspepsias of infancy—one that does not merely coin new names, but has brought in new and suggestive ideas. The term "nutritional disorder" is the key to the understanding of this classification. It is a deliberate enlargement of the old and narrow term "dyspepsia," and expresses disturbance not only in the digestive functions but also in that of assimilation, and in that mysterious chemistry of the assimilated materials which is called metabolism. "Nutritional disorder" is thus a term well adapted to convey the wider meaning. The causes that produce any kind of nutritional disorder are given in three main groups—"ex alimentations, ex infectione, et ex constitutione." Thus, of nutritional disorders, we have those produced by errors in the food, quantitative or qualitative, by toxic or infective agents, or by inborn weakness in the body, and these factors may act singly or in varying combination. The third volume fully details this scheme of classification.

⁴ *Tissue Culture*. By Albert Fischer, M.D. With an introduction by Alexis Carrel, L.B. B.S. M.D. Sc.D. London: W. Heinemann (Medical Books) Ltd. 1925. (Sup. rev. 8-0 pp. 310, 70 figures, 1 plate, 21s net.)
⁵ *Des Kindes Ernährung, Ernährungsstörungen und Ernährungstherapie*. Von Professor Ad. Czerny und Professor A. Keller. Zweite vollkommen umgearbeitete Auflage. I. Band 2 Teil und II. Band 1 Teil. Leipzig und Wien: F. Deuticke. 1925. (Sup. rev. 8-0. Band I pp. vii + 1078, 132 figures, 4 dollars. Band II pp. 368 G.M. 18.)

with its divisions and subdivisions, and does so with a mastery and confidence begotten by much previous exposition of the subject and by the wide support which these new ideas have already received. It brings the story to the end of the food injuries and the infections, and begins that of the constitutional disorders with an account of the exudative diathesis. It is broken off, and will no doubt be resumed in a later instalment. To enter into a critical examination of this classification of nutritional disorders in infants would therefore be out of place. It has provided a new line of approach to a difficult subject, has stimulated pathological research, and has suggested new methods of treatment.

MONUMENTA MEDICA

THE various volumes of the *Monumenta Medica*, a series of reproductions of medical works of historical interest, under the general editorship of Dr HENRY SIEGIST, are appearing with regularity. Sixteen months ago (1924, vol. II, p. 19) we had occasion to notice the reproduction of the *Fasciculus Medicinæ* of 1491, associated with the name of Johannes de Ketham, with an historical introduction by the editor of the series and a translation by Dr CHARLES SINGER. In a second volume Dr Singer, who dates his preface from the Anatomical Institute, University College, has done a like service for the Italian collection of medical treatises known as *Fascicolo di Medicina* (Venice, 1493),⁶ one of the most beautifully illustrated books of the fifteenth century. Dr Singer has carried through his task with all his accustomed learning and zeal for the history of medicine. In Part I he gives a description of the *Fascicolo*, a discussion of its editions, art, language, sources, and influence, a translation of the *Anatomia* of Mondino di Luzzi, an account of medieval anatomy and physiology, and an atlas of illustrative figures from manuscript and printed sources. The Facsimile, which occupies Part II, gives an extremely good reproduction of the beautiful Italian lettering of the age which imitated the handwriting of the humanists. The legends of the figures are in very clear Gothic type, the figures include some of the best examples of the woodcutter's art of the fifteenth and sixteenth centuries. Dr Singer's translation of Mundinus, his account of medieval anatomy and physiology, and the atlas of anatomical figures from medieval manuscripts and books, are of the greatest general interest and importance in relation with the history of anatomy. Among the illustrations reproduced from the *Fascicolo* are one from the library of Pietro de Montagna: a microscopic consultation scene and a circle of urine glasses, male figures marked to show the locality of the diseases, and then relation to the signs of the zodiac, a plague scene and most important of all, the dissection scene printed in four colours—black, yellow, green, and red—in which the young lecturer is seated at an elaborately carved desk. He is intended presumably to represent Mondino at Bologna.

NOTES ON BOOKS

THE cult of health is producing a vast literature addressed to both professional and lay readers. *Personal and Community Health*,⁷ by Mr C. E. TURNER, associate professor of biology and public health in the Massachusetts Institute of Technology, is a condensed encyclopædia on the subject. In his preface the author says that his book has been prepared for the student at the university, college, or professional school. Apparently this does not mean the medical student but students in every department, for we are told that "the public health is considered from the standpoint of what the college or professional man, who is not a sanitarian, needs to know in order to protect his family and meet his responsibility as a citizen. But, if so why should the reader be worried by the intricacies of Ehrlich's theories of immunity. On the other hand, if the book is really intended for the medical student some of the advice offered seems redundant.

gators had been concerned with problems raised by previous studies. Such inquiries involved tedious and long continued experiments. Of the papers published during the year two were concerned with tar, one by Dr Cramer, on the influence of innervation on tar carcinogenesis, indicated a definite retardation of the onset of cancer in skin areas deprived of their nerve supply. Nerve regeneration, however, spreads into the denervated area in the later stages of the experiment, and the exact interpretation of the result is obscure. Dr Findlay, in another paper, described the results of a single application of hot tar to the skin of the back in 150 mice. The experiment was an attempt to reproduce in animals the occurrence of epithelioma in tar workers at a short interval after accidental tar burns in sites not usually affected by this form of industrial cancer. Of the mice experimented on by Dr Findlay, in three only did typical carcinoma develop. In Dr Murray's opinion the outstanding event of the period under review had been the publication of the researches of Dr W E Gye and Mr Baird into the etiology of malignant growths (*Lancet*, 1925, vol ii, p 104, and *British Medical Journal*, 1925, vol ii, pp 174 and 189). Dr Murray pointed out that the essence of Dr Gye's conception was that malignant growth results from the occurrence of two factors—an ultramicroscopic microbe and an unstable chemical factor. The direct evidence of this dual origin had been obtained from the Rous fowl sarcoma and for a transplantable sarcoma of the mouse. For other tumours the evidence was indirect, cultures of these yielding the ultramicroscopic microbe, the unstable chemical factor being supplied by an extract from the Rous fowl sarcoma. The delicate racial and tissue specificity governing the transmission of malignant new growths must therefore, it was concluded, attach to the labile chemical factor, and not to the microbe. One of the gravest objections to previous forms of the parasitic hypothesis of cancer was therefore met. It was a legitimate source of satisfaction to the Fund that it had been able to supply for Dr Gye's experiments propagated animal tumours sufficiently exempt from ordinary bacterial contamination. The Fund's laboratory had undertaken to test the validity of the hypothesis. The new problems being susceptible of direct experimental study, speculation and anticipation should be strongly deprecated. Dr Murray expressed his indebtedness to Mr J E Baird, F.R.S., from whom he had received most valuable help and encouragement in the installation and equipment of the apparatus necessary for a repetition of his published visual observations by high-power dark-ground microscopic methods.

Adoption of Reports

Sir HUMPHRY ROLLESTON, chairman of the Executive Committee, moved the adoption of the annual report. He congratulated the director, Dr J A Murray, on his election to be a Fellow of the Royal Society, and gave a short account of the researches mentioned in the director's report. He referred also to the researches of Dr A M Begg under the Atholstan grant. His investigation on the Rous fowl sarcoma and the infective lymphosarcoma of the dog had inevitably received a new orientation since the publication of the work Dr W E Gye had done for the Medical Research Council. Since the death of Dr Russell, who took a keen interest in the work, Dr Begg had the advantage of close association with Dr Gye, and the investigations were progressing satisfactorily. Professor A E Boycott seconded the motion, which was carried unanimously.

In moving a vote of thanks to the Executive Committee, the President, the Duke of Bedford, said that the list of workers to whom material had been supplied from the Fund's laboratory showed that it was able to assist in the investigation of cancer in laboratories other than its own. Such assistance involved the staff of the Fund in very laborious work and took up a great deal of their time, it thus entailed a considerable addition to the working expenses. Such an increase in expenditure was a legitimate source of satisfaction, inasmuch as it meant furthering research throughout the Empire. On the motion of Sir GEORGE MEYERS, G.C.M.G., F.R.C.S., seconded by Mr LUDWIG NEUMANN, a vote of thanks was recorded to the Duke of Bedford for presiding at the meeting.

Nova et Vetera.

A TWELFTH CENTURY PHYSICIAN IN THE LAW COURTS

VOLUME 14 of the publications of the Pipe Roll Society contains 'the earliest plea rolls, the earliest solemn judicial records that are preserved in the National Archives'—plea rolls of the reign of Richard I. They are here printed with an introduction and notes by Professor F W Maitland.

One item only of medical interest is found in these pleas, it occurs in the fourth roll, which has been ascribed to the Bedfordshire and Buckinghamshire eyre of 1195. Extended it runs as follows:

Translation

Assisa venit recognitura et Oliverus filius Rannulphi Haki et Simon medicus disseisinerunt Willelmum filium Simonis et Sibelle uxoris sue injuste et sine iudicio de libero tenemento suo in Clifton infra assisam. Simon medicus dicit quod ipse disrationavit illud tenementum versus Oliverum in Curia Domini Regis per concordiam inter eos factam. Et inde protulit iuramentum inter eos. Et Oliverus venit et idem testatur et dicit quod disrationavit terram illam per assisam de morte antecessi versus matrem suam et juniorem fratrem suum et ipsam Sibellam sororem suam post obitum patris sui. In qua terra ipsi injuste se tenuerunt et inde producit Milites de Comitatu qui eidem assise capiendi interfuerunt. Et hoc idem testantur Willelmus et Sibella sed dicunt quod postquam idem Oliverus disrationavit illam terram dedit eis terram illam et homagium inde cepit et inde ponunt se super visnetum.

The assize comes to recognize if Oliver son of Ralph Haki and Simon the physician disseised William son of Simon and Sibella his wife unjustly and without judgement of their free tenement in Clifton within the assize. Simon the physician says that he denigned (i.e., proved) it to be his by process of law that tenement against Oliver in the Court of the Lord King by concord made between them and thereon he produces the circograph made between them. And Oliver comes and bears witness to 'the same and says that he denigned that land by assize of *mort d'ancestor* against his mother and younger brother and against this Sibella his sister after the death of his father in which land they unjustly held themselves and thereon he produces the Knights of the Shire who were present at the taking of the same assize. And William and Sibella bear witness to this but say that after the same Oliver had denigned that land he gave the land to them and took homage for it and they put themselves on the neighbourhood touching this.

The Clifton here referred to would appear to be the parish of Clifton-Reynes in Bucks, near Olney. In Lewis's *Topographical Dictionary of England* it is stated that the principal manor was given by the Conqueror to Robert de Todeni, and it later passed into the family of Revnes from which the parish takes the adjunct to its name. I have not got a copy of the Buckinghamshire Domesday to which to refer, but I suspect that Robert de Todeni should really be Ralph, who is stated to have been the Conqueror's standard-bearer at Hastings. I am not sure of this.

It is a matter for regret that I am not able to give the "concordium" made between the parties. I have searched vol 1 of Hunter's *Finis sue Pedes Finium*, which contains the Buckinghamshire final concords from 1195 to 1214, without success, and neither of the two volumes of the Pipe Roll Society's publications which deal with these final concords contains any reference to Simon the Physician. In fact very few medical men find mention in these fines perhaps they cured their clients instead of having lawsuits (real or fictitious) with them!

Maitland says that the "assize of novel disseisin is the most popular of all actions. A time is limited within which the disseised person must bring the action." "In some cases the limiting period was King Richard's coronation, but very often this period is not definitely mentioned in the record, but is implied by the phrase *infra assisam*, within the assize, i.e., within the time limited for the assize."

I have to thank Mrs Stenton for correcting my extensions of the Latin of this deed, and for the translation and for much kindly help.

R R JAMES, F.R.C.S.

CHARCOT AND THE SALPÊTRIÈRE

WHEN Professor Charcot died unexpectedly in August, 1893, we wrote of him that "in the Salpêtrière with its 4,000 beds he found a quarry of clinical material out of which he was able to raise an edifice of intellectual achievement, at once solid in structure and artistic in finish, which will form a *monumentum aere perennius* to his memory." The day of Charcot's birth was November 29th, 1825, but the centenary was commemorated by anticipation in Paris at the end of last May, and in London on June 15th at the Royal Society of Medicine. Dr. Fairclough Buzzard, President of the Section of Neurology, in the course of an address on Charcot's life and work at the centenary celebration in London, referred to the large collection of Charcot's publications which had been arranged for inspection by Mr. W. G. Spencer, the honorary librarian of the Royal Society of Medicine. The collection showed that Charcot's writings were numerous, and dealt not only with neurology but with other branches of medicine. They proved that their author was a pioneer of no ordinary qualities, and were important for the history of medicine. He was a supreme exponent of the science and art of medicine, and probably the finest teacher of modern times.

An additional centenary memorial, and one which illustrates the truth of the sentence quoted from our obituary notice of Charcot, has now been erected in a fine volume by Professor Georges Guillain and Dr. Paul Mathieu on the history of the Salpêtrière, to which Charcot was appointed medical officer in 1862. It was here that he commenced in 1866 his weekly clinical lectures on which his reputation mainly rests, sixteen years later he became the first occupant of a chair of clinical neurology at the Salpêtrière, an appointment he held until his death.

The institution, converted by Charcot into the chief neurological clinic of Europe, owes its name to the powder factory which, under the name of Le Petit Arsenal (subsequently changed to La Salpêtrière), was built on its present site in the reign of Louis XIII in what was then a suburb of Paris. Owing to the great increase in the number of beggars and unemployed following the disturbances of the 17th century, the building was handed over by a royal decree to the celebrated philanthropist Vincent de Paul, who devoted all his energies to its organization for the reception of this class of persons. Immediately after the promulgation of this royal edict in 1656 Cardinal Mazarin caused to be erected within the grounds of the institution the building still bearing his name. Mendicancy was henceforth strictly threatened with severe penalties. In 1657 the Salpêtrière contained as many as 800 inmates, the insane being prohibited, and those giving hospitality to mendicants were

isolated from the rest from the first. In 1680 another building was added, which became notorious as the prison of La Force for the reception of prostitutes and criminals of various grades. It was here that were confined the victims of convulsive hysteria who had previously thronged to the tomb of François, deacon of Paris, in the Saint-Médard cemetery, Marion Lescaut, heroine of the Abbe Prevost's celebrated romance, Madame de Valois, notorious in connexion with the diamond necklace, and Thénioigne de Mericourt, the well known figure in the revolution of 1793.

In the course of the seventeenth and eighteenth centuries the Salpêtrière became the largest almshouse in Europe, containing as it did five to eight thousand inhabitants at a time when the population of Paris did not exceed half a million. A statistical table of 1679 shows that, in addition to beggars and aged and infirm women, the institution contained 148 epileptics and 100 insane women and girls.

As is well known, the insane, until the time of Pinel, were

very badly treated at the Salpêtrière, where at first only the supposedly incurable cases were sent, the rest being kept at the Hotel-Dieu. In the course of 1791 the curable insane were admitted to the Salpêtrière, and their condition was considerably improved, thanks to Pinel, of whom the well known picture, by Tony Robert-Fleury, releasing them from their chains, adorns the present lecture room. Towards the end of the eighteenth century the charitable purpose of the institution was extended by the addition of a maternity hospital for the reception alike of the married and unmarried.

After the beginning of the nineteenth century prisoners ceased to form part of the population of the Salpêtrière. In 1848 the young female idiots were separated from the other patients,

and in 1872 the epileptics were placed in a building distinct from that of the insane.

Charcot's administrative work in the Salpêtrière included the organization of laboratories for the study of pathological anatomy and physiology, the construction of a small outpatient department, and the erection of the amphitheatre in which his celebrated lectures were given. Approaching the then existing chaos of nervous symptomatology as a skilled anatomist, physiologist, pathologist and an expert in medicine generally, he speedily replaced the mists of speculative dogmatizing by a system based on ascertained fact and logical deduction. In his earliest Sunday lectures he demonstrated his discoveries in the pathology of nervous diseases to crowded and enthusiastic audiences; later, from the chair of neurology, he enunciated in his famous Tuesday lectures the principles of the new science which he had created.

To-day the Salpêtrière, besides being the most important neurological centre, continues to be the largest almshouse in Paris, with its 2,696 beds for the aged and infirm, so that the original character of the institution as a home for the poor is still preserved. It also contains a central laundry, needle room, and ambulance department for several hospitals attached to the Assistance Publique.

ACUTE INTESTINAL OBSTRUCTION

THE report of the discussion on acute intestinal obstruction, in the Section of Surgery at the Annual Meeting at Bath, published in this issue (p 993) ought to make a very wide appeal. In none of the emergencies of surgery is there more urgent need for the co-operation of the general practitioner with the surgeon, whose special skill will be useless if the case is sent to him too late, and in none is it of more importance that the public should be educated to realize how imperative is the necessity for early surgical relief. Without endorsing Sir William Taylor's wholesale indictment of the general practitioner, we must all agree that no condemnation can be too strong for the man who wittingly leaves an obstruction unrelieved for an hour longer than is necessary. The real difficulty lies in the early recognition of these cases—a difficulty which even surgeons of wide experience have not always escaped—and Mr Sampson Handley carried the attack into the opposite camp by declaring that the surgeons themselves are at fault for the lamentable textbooks they have written! It is indeed true, as he said, that too much stress has been laid on the more dramatic features of the later stage, when constant vomiting and toxic absorption have lined in the shadows of impending death, and too little on the vital importance of complete constipation and of the patient's own conviction that he is obstructed—a conviction which is often the first symptom of all, and which the surgeon will neglect at his peril.

Sir William Taylor, indeed, went on to demolish his own thesis, that no improvement has taken place in the treatment of obstruction in the last quarter of a century, by producing his own splendid statistics of intussusception, in which he could show 81 cases with only 3 deaths, this is a fine tribute to his skill and to the promptness and acumen of the practitioners who sent the cases up. Later in the discussion Mr Max Page produced statistics from St Thomas's Hospital, showing that in twenty years the mortality of intussusception had dropped from 40 to 9 per cent, while cases of carcinoma of the intestine were now admitted at such an early stage that few of them came under the heading of acute obstruction at all.

Perhaps the greatest advance in the technical treatment of obstruction is the large use which is now made of drainage of the jejunum. In the hands of many surgeons, and even in the most desperate cases, this method has given very remarkable results. An incision is made through the left rectus muscle above the umbilicus, and through this a loop of the jejunum, as near to its origin as possible, is brought out. Into it is fastened a tube of 7 or 8 mm diameter, after the method of Senn's gastrostomy, except that only one or two purse string sutures are used, so as to avoid too much subsequent narrowing of the intestinal lumen. The intestine is then returned within the abdomen and fixed by two catgut sutures, one on each side of the tube, to the parietal peritoneum and posterior sheath of the rectus. By this means the distended intestines can empty themselves of their poisonous contents, while they can be readily irrigated with

sodium bicarbonate solution and glucose, counteracting acidosis and supplying carbohydrate to the patient. The tube can be removed in forty-eight hours, and if it has been brought out through the omentum, as Mayo suggests, there is no need to suture the opening. Even in secondary peritonitic obstruction the method, first used by Victor Bonney, has given brilliant results. But, as Mr Grey Turner pointed out, it must be used as an adjunct to other procedures, and not as an isolated method of treatment. Except in the most desperate cases relief of the obstruction itself must be secured by caecostomy or some other means. Where a loop of bowel has been released from strangulation Mr Sampson Handley urged the importance of a precautionary lateral anastomosis above the loop. In these cases, although the loop may retain its vitality, there is always a risk that it may remain paralysed, and that the patient may die of consequent obstruction before the loop can regain its peristaltic power. This risk is avoided by a short-circuit which Mr Handley performs, almost as a routine, with very satisfactory results. The method may be used with advantage in strangulated hernia, in obstruction by bands, in obstruction by gall stones and foreign bodies, and, in fact, in any case in which, after the relief of a mechanical obstruction, there is a possibility of paralytic ileus. Few surgeons who have been faced by this disaster will not agree that such a precautionary measure, which can be carried out rapidly and with little disturbance of viscera, is well worth while.

The discussion was remarkable for the great mass of statistics collected from various large hospitals, which were presented at the meeting by surgeons from the various hospitals. A schedule drawn up by Mr Souttar had been distributed, on which certain details of each case could be recorded with very little labour, and from these each hospital constructed a table on an identical plan. These tables were finally brought together to afford combined statistics of over 3,000 cases—a number sufficient to show with some authority the incidence and results that may be expected at the present day in this country in hospitals of the first class. In individual hospitals the variation is considerable, the admissions of intussusceptions, for example, being affected by the neighbourhood of a children's hospital, while some hospitals appear to make a specialty of strangulated hernias, and others to elude them entirely. In the combined table (p 1000) these variations are fully balanced. A glance at the table, or still more at the chart (p 1001) which is founded upon it, will reveal at once important results. Of these one of the most interesting is the extraordinary frequency of acute idiopathic intussusception in infancy, for it actually accounts for one-fifth of the total number of cases of obstruction from all causes and at all ages. Excluding external hernias, it formed 40 per cent of the total number of cases, and in actual numbers it was only surpassed by femoral hernia. When the fact is taken into account that practically the whole of these cases occur in the first year of life the importance of the condition as a disease of infancy can scarcely be overestimated. Of other causes of obstruction those due to adhesions occurred almost equally at every age, whilst carcinoma and gall stones only appeared late as causal factors, becoming most prominent in the sixth and seventh decades.

There can be no doubt of the great value to the profession of such a discussion, and of the combined work which its preparation entailed. It enables us to take stock of our position, it tells us where we are, and if we feel that we ought to be able to show better

results it stimulates us to further effort. Every hospital in the country ought to compile its own statistics with those presented here, while there are few surgeons who will not learn something from the various technical methods described by masters of their art. But the lesson which comes with reiterated force in every line is that time is the essence of the problem. It is in the hands of the general practitioner that the future hope of improvement in results really lies. It is for him to learn, as indeed he is learning, to diagnose obstruction before vomiting and distension have made the diagnosis simple and the treatment impossible, and it is for him to teach his clients that in this of all conditions the most fatal policy is to "wait and see."

ON EMBOLECTOMY

We publish on another page (985) the report of a case which appears to be the first successful embolectomy achieved in this country. An account of the cases which appeared prior to 1922 was published in that year by Key, Jefferson of Manchester in the present issue brings the literature up to date, and includes an analysis of the later cases. Sweden stands far ahead of any other nation in successes. France can claim two, the United States two, and some other countries one each. Considering the relatively small population of Sweden this state of affairs calls for some explanation. As a matter of fact the reason is simple enough. It is to be found in the interest E. Key of Stockholm has taken in the subject and the enthusiasm for this new method of treatment which appears to have been aroused in the practitioners of that country. Left to themselves most cases of peripheral arterial embolism end in gangrene of the limb. It is important to recognize the fact that an embolism is more apt to lead to gangrene than is ligation of the vessel, because in the former secondary thrombus formation soon plugs the opening of the collaterals and may be very extensive. In the case reported in this issue the thrombus was lodged in such a position as to block not only the main arterial current of the arm, but also an important collateral, the superior profunda artery. In such a condition as this the chances of survival of the limb are distinctly small if the clot is not immediately removed, as was successfully done in this case. In a few hours thrombosis progresses further and changes occur in the inner coats of the vessel, so that after twenty-four hours have elapsed very little hope seems to remain of re-establishing the circulation. Even in these late cases some good may come of the attempt, particularly in embolism of the larger vessels. For though gangrene may not be prevented it may be made to affect a smaller area than would otherwise have been the case. It is, however, probable that the vast majority of these late cases had better be left alone.

A study of Table II in Jefferson's paper shows that the majority of successes have attended operations undertaken within the first five hours. This means that embolectomy is an operation of extreme urgency. The person, therefore, who has to be interested first and foremost is the general practitioner, and he will, we think, be convinced of the advantages of the new method. Embolectomy has been attempted in England before. In 1907 Sampson Handley reported an attempt on an embolism at the aortic bifurcation, done twenty-four hours after lodging. Retrograde catheterization along branches of the femoral artery was employed, but the patient died the next day.

Moynihan then recorded a case of his own where he had removed a clot from the popliteal artery, but the patient died five days later. Gordon Watson had a partial success in 1913. Embolectomy was done six hours later. On exposing the femoral artery the clot slipped away, and was arrested again in the popliteal vessel. No more was done, and amputation had to be performed later for the usual gangrene. The patient recovered. Collective experience has since taught us that in a case like this a second exposure should be made at once over the popliteal space.

Arterial surgery is by no means as difficult as some imagine. Ordinary care, delicate handling, avoidance of tearing or bruising of the inner lining of the artery, the use of an anticoagulation fluid, and of fine silk and fine needles which take a good grip of the vessel wall without piercing the intima—these are the main essentials. It will be a surprise to all whose first experience it is how easily three or four interrupted sutures will effectively close a slit in the wall of a large artery. It is most important that these facts should be realized, since the urgency of operation means that some cases must be done in out of the way places, and perhaps by the general practitioner surgeon. The femoral and popliteal vessels are easier to open than the brachial and axillary, but fortunately the former are the commonest sites of lodgement. Operation on the aortic bifurcation and iliac artery may tax the resources of the most able and experienced surgeons, and had better be left to them. Valuable hours must not be lost pondering on the case, the possibly advanced age of the patient is no contraindication. Local anaesthesia is very advisable. Should the operation fail, even should the vessel have to be ligatured owing to some mishap in technique, the patient will be no whit worse off than he would have been had the operation not been attempted. For these reasons, because there is everything to gain and little if anything to lose by operation, it appears that the operation of embolectomy is winning a definite and valued place.

QUEEN ALEXANDRA

No one of late years in any walk of life has more impressed the heart of the country than Queen Alexandra. The impress of great minds, of doughty deeds, of daring leadership—each in its own sphere receives its due meed of fealty. But there is no character which carries with it a wider sway in any circle, whether large or small, than the possession of a gentle and kindly spirit. This spirit Queen Alexandra possessed in exceptional measure, and that sovereignty, added to the sovereignty of her position, won for her a regard in the hearts of the peoples of these lands that will not easily be forgotten. Youth, beauty, and romance assured the Danish Princess a warm welcome to these shores more than sixty years ago. Many a queen has been as warmly welcomed in this and other lands, but to few has it been given to establish themselves so firmly in the perpetual regard of the land of their adoption. The transplantation of a young girl from the quiet home life and court of a small northern kingdom into the maelstrom of the court of the capital of a great empire is attended by no small risk. The warmer the reception, the greater the attention attracted, the higher the station attained, the more is that risk increased. But never through all these years, whether as Princess, Queen, or as Queen-Mother, has there even been a breath of hostile criticism, but only a grateful acknowledgement of the kindness which every action proclaimed. To Queen Alexandra we as medical practitioners are deeply indebted. In its work for the

public and the medical profession is ever beholden to those persons of public spirit and human feelings who are ready, often at no small sacrifice of personal comfort, to take upon their shoulders the burden of carrying into effect, or of securing the public recognition and acceptance of, measures that we see are necessary but cannot unaided achieve. Queen Alexandra, by her enthusiasm for good nursing, has left an indelible mark upon the medical work of this generation. Her action at the time of the South African war, which culminated in the formation of the Queen Alexandra Imperial Nursing Service, was a bright spot in the tragedy of that campaign. Everyone who had experience of the appalling epidemic of typhoid and dysentery which ravaged our troops and filled the great military hospitals to overflowing will assert that had it not been for the excellence and amplitude of the nursing service that story would have been far darker than it was. The lightening of that page was due to Queen Alexandra. Her interest in hospitals of all kinds was never-failing. No social claims took precedence over the call of a hospital for her services. And what she did was done with a grace and thoroughness that made it invaluable. Her interest extended beyond public occasions. She would make visits, unexpected and unheralded, that were a source of inspiration to every worker in the hospital. Even in these last years of declining vigour and health she did much to make "Rosa Dry" a national tribute to the hospitals. It is but a few months since King George and Queen Mary paid the British Medical Association the signal honour of opening its new House, and thus gave one more proof of Their Majesties' warm-hearted support for all good medical work begun, continued, and ended in the service of humanity. To the King, the Patron of our Association, we would tender our respectful sympathy in his bereavement. The higher and more isolated the station of life, the dearer and more treasured must be the inner ties of family, and the greater the loss of any of those precious links.

MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

At the meeting of the Council of the Royal College of Surgeons of England held on July 30th last (as recorded in our issue of August 8th, p. 277) the terms of a petition for a Supplementary Charter were considered and approved, and it was decided that the further steps to be taken in the matter should be considered at the quarterly Council meeting in October. The main purpose of the proposed Supplementary Charter is, in general terms, to enable the Council to make improved arrangements for certain examinations. The great increase in recent years in the number of candidates for Fellowship and Membership and for the Licence in Dental Surgery has caused a heavy call to be made on the Court of Examiners, and so much time has been taken up in examining as to make it impossible for them to carry on their hospital and other duties. The Council is accordingly seeking power to increase the number of members of the Court of Examiners and to relieve them from the duty of examining for the L.D.S. As these changes cannot be made under the existing charters, a Supplementary Charter is needed to give authority for them, and also to give power to admit women Fellows and Members and Licentiates in Dental Surgery on the same terms and conditions as men, and with the same rights and privileges. The form of petition and draft Supplementary Charter appear in the current *Calendar* (1925) of the College. As might be expected, the opportunity thus arising has not been overlooked by the Society of Members of the Royal College of Surgeons of England, whose leaders have for some thirty years made the annual meetings of Fellows and Members an occasion for pressing the claims of the Members to a share in the government of

the College. We publish elsewhere this week (p. 1037) a report of this year's meeting, held on November 19th when Dr. Haden Guest, M.P., moved the customary resolution affirming the desirability of admitting Members to direct representation upon the Council of the College, and urging the Council, in its application to the Privy Council for a Supplementary Charter, to insert a provision therein for some representation of Members as such upon the Council. The motion, like so many of its predecessors, was carried. The President, in his reply, refrained from traversing any of the remarks made by the mover and seconder of the resolution. The Council, he said, intended to give the matter its very earnest consideration, and that without any delay, before the Supplementary Charter was sent in to the Privy Council. This pronouncement was received with gratification by the representatives of the Society of Members, whose speeches, it may be added, had been marked by an urbanity not too noticeable on some occasions in the past. We understand that before the Council meeting communications on the subject had already passed between the society and the Council of the College. On September 28th the society wrote to the Council asking to be received in deputation, and on November 12th a deputation of six, headed by the president of the society (Dr. Redmond Roche), was received at the College by the Council, all its twenty-four members being present. After recapitulating the history of this movement from the time of the Charter of 1843 to the present day, Dr. Roche appealed to the Council to insert into its draft petition for a Supplementary Charter such clause or clauses as would provide a reasonable representation of Members as such. At the conclusion of the annual meeting on November 19th the members of the Council present met in committee, and it is understood that at the Council meeting on December 10th the matter will be decided by the Council in full session. The question is at least as old as the Royal Charter of 1843, under which, *inter alia*, a portion of the Members of the College became Fellows, Fellows alone became eligible for membership of the Council, and the election of members of Council was placed in the hands of Fellows. Before 1843 the Council of the College was self-elected, and the College consisted merely of Members. It is a matter of historical argument as to when the rights of control inherent in membership of the pre-existing companies were abrogated, but we do not think it is in dispute that for many years before the Charter of 1843 the Members, as such, had lost whatever share they may at any time have had in the control of the institution. This aspect of the matter was argued at considerable length and with great skill by a former Editor of this *Journal*, the late Mr. Ernest Hart, in a statement made by him in 1887 as spokesman of a deputation of Members of the College to the Lord President of the Privy Council. For one reason or another, however, the movement for representation of Members of the College has never aroused widespread support among those chiefly concerned.

MEDICAL SCIENCE AND AVIATION

THE appearance of a new branch on the tree of medical science is a phenomenon worthy of attention, even in these days when the leaves and twigs of new discoveries are springing so rapidly from the older branches. The essential importance of the psychological and physiological factors in aviation has become obvious, and the new developments of medical science in this connexion, which first became manifest during the later stages of the war, are rapidly increasing both in number and complexity. One of the earliest tests introduced to assess the flying efficiency of a pilot was the measurement of his "respiratory capacity", this involved the raising of the body weight on to a chair five times in fifteen seconds. If the pulse rate increased

by thirty-six beats or more, and the time taken to return to the normal exceeded thirty seconds, then the pilot was looked upon with suspicion.¹ There followed the introduction of the "word association" test used in psycho-analysis, which, it was thought, would indicate in some degree psychological efficiency. Other methods of examination were devised in rapid sequence, and on September 18th, 1920 (p. 443), we referred to the work of the Air Medical Investigation Committee, which laid especial stress on the use of oxygen, the estimation of self-control, and the study of emotional and physiological conditions. In the next year the first International Air Congress was held in Paris to discuss these new developments, a second International Congress was held in London in 1923, and a third was held in Brussels from October 6th to 10th last. It was of exceptional medical interest, and several of the papers read have been published in the *Journal de Médecine de Bordeaux* for October 25th. Major J. Beyne, of the French Army, after a very careful study of psychological tests in relation to flying, has come to the conclusion that in testing the pilot's response to stimulation the time of his reaction is of considerably less importance than the accuracy of his response. Major Beyne states that the healthy functioning of the nervous system cannot be assessed accurately by examination of the isolated working of any elementary physiological or psychological process, and that, therefore, no one test is capable of furnishing a rational method for selecting aviators. While it is important that the pilot should react quickly, it is of even greater importance that he should have the ability to respond correctly to stimuli which do not occur one at a time, but vary in their intensity and nature. Preliminary testing must, therefore, include exposure to variously grouped stimuli. Some system should be devised of recording the results of these tests, of assessing their value, and of correlating them so as to provide a standard of efficiency. By using the number of stimuli in the test as the denominator of a fraction and the number of correct responses as its numerator, a figure is obtained which Major Beyne believes will prove to be of definite value as a measure of the proficiency of the pilot. These tests are performed in an apparatus rather similar to that described by Flight Lieutenant G. H. Reid, and referred to in our issue of March 15th, 1924 (p. 481), a model of such an apparatus was shown at the Wembley Exhibition. At the same congress Dr. G. Ferry, who was a distinguished French aviator during the war, described his sensations during an accidental spinning nose-dive, in which a disaster was only averted by a chance look at the dial registering the revolutions of his engine. As a result of this experience he advises aviators to rely more upon their instruments than upon their special senses. This seems to be rather opposed to the prevalent teaching in England, where it has been found that during a rapid descent the aneroid adjustment of the altimeter is slow to respond, and may, indeed, be registering a height of 1,000 feet above the actual. Group Captain M. Flack, R.A.F.M.S., speaking at the congress, emphasized the great value of the Reid apparatus for testing the psychomotor reactions of the pilot and his aptitude to fly. He prefers to assess an aviator's efficiency by observing the reactions brought out by this apparatus, and the effect of physical effort on the heart, pulse, and arterial pressure, combined with a test of the respiratory capacity. By examination of the circulatory system it can be discovered, moreover, which pilots will suffer from vertigo when flying especially when "stunting", which will be liable to syncope at high altitudes, and which will be unduly nervous. For this test the pilot is seated in a revolving chair, which is made to turn ten times in twenty seconds. In good pilots the pulse rate and pressure are not much affected, but in those subject to airsickness the

pulse rate quickens from 84 to 144 a minute, the systolic pressure increases from about 126 to 158-172 mm of mercury, and the diastolic pressure from 82-88 to 98-102 mm. In those pilots likely to suffer from syncope this rotation causes a characteristic fall in the diastolic pressure. In the various type the pulse rate and blood pressure increase before the test, and may or may not be affected by the rotation. Dr. C. B. Heald, the medical consultant for civil aviation in England, impressed on the congress that the general life and work of a pilot had an important bearing on his professional ability, a quiet and regular daily routine rendered him more capable of resisting fatigue and of dealing with sudden emergencies, particularly if he was shielded as far as possible from discomfort while flying. As in modern industry, so in aviation both physiology and psychology have been called upon to play a part the importance of which can hardly be exaggerated. These new openings for medical practice and medical research will doubtless attract many of those who are on the threshold of professional life, and who will welcome the opportunity of sharing in the pioneer work that still remains to be done.

POISONOUS DOMESTIC CLEANING FLUIDS

WE publish elsewhere a letter from Dr. H. R. Oswald, coroner for the Western Division of London, drawing attention to the apparent inadequacy of our poison laws in one respect. We know of no country in which the sale of poisonous substances for industrial or economic use is restricted to pharmacists, as Dr. Oswald suggests. In the United States of America the law is less restrictive than in Great Britain, extending little beyond the prohibition of the drugs comprised in the British Dangerous Drugs Act. Apart from that Act, which relates only to drugs producing addiction or craving, our legislation has been aimed at preventing the criminal use of poison and safeguarding the public from accident, but always with due regard to the convenience of legitimate users. Before the passing of the Pharmacy Act the only restriction in existence related to arsenic. It was called into being, we believe, owing to a barrel of arsenic having been mistaken for a barrel of flour. By the Pharmacy Act of 1868 the sale of certain poisons named in a schedule to the Act was restricted to registered chemists and druggists. The schedule can be enlarged in accordance with powers conferred on the Privy Council. These powers have habitually been exercised. Additions to the schedule have been made whenever a new danger appeared. The reservations made to remove difficulties of purchase in cases of legitimate requirement may appear not infrequently to be incongruous, but are quite rational when viewed with full knowledge. Carbolic acid was first scheduled as a poison when it was found that there was danger connected with its very general use as a disinfectant, but the regulations are so worded as to apply still only to liquid preparations containing more than 3 per cent of the substance. A powder containing carbolic acid or any dry mixture containing it may be bought without restriction. Even the strong liquid preparations may be sold without restriction when supplied for use as a sheep wash or for other agricultural or horticultural use, provided that they are suitably labelled. The balanced view held by the administrative authority is plainly illustrated by the form in which the dangerous products of tobacco are scheduled as poisons, it reads "Any preparations or admixtures of tobacco (other than tobacco prepared for smoking and snuff) containing the poisonous alkaloids of tobacco." Zinc chloride is similarly treated, the exceptions applying to preparations of zinc chloride intended to be used for soldering or other purely industrial purpose. It has not hitherto been deemed necessary to make the corrosive acid—nitric, sulphuric, and hydrochloric—subject to the restrictions governing scheduled poisons. They may be sold by

¹ BRITISH MEDICAL JOURNAL 1920, vol. II, p. 533.

anyone, but the bottles in which they are supplied must be distinguishable to the touch—that is, ribbed or fluted—and they must be labelled with the word "Poisonous." Dr Oswald's communication appears opportune. It was swiftly followed by a report in the *Times* of the death of a woman from inhalation of the vapours of strong nitric acid while using it to clean some brass-work and copper vases. Having regard to the many amendments of recent date to our poison regulations, we do not think it can be said that there has been lack of official attention to the subject. Nitric acid is, however, attended by an unusual danger in the effect of its fumes on the lungs. We remember several instances of death from its inhalation. It would seem that the suggestion to make nitric acid a poison under the Act presents a case for serious consideration. Dr Oswald would add hydrochloric acid (spirits of salts), and also salts of lemon—a mixture of acid potassium oxalate (or binoxalate) and potassium tetroxalate.

THE "TALKING FILM" IN MEDICAL EDUCATION

THE "chief image of truth" notes "may find himself superseded by the invention brought to the notice of the Electro-Therapeutics Section of the Royal Society of Medicine by Dr C. B. Heald last week. The De Forrest "Phonofilm" is a combination of a moving picture with a record of sounds, so that the image on the screen has its verisimilitude heightened by the accurate reproduction at the same time through "loud speakers" of the words or music or other sounds which accompanied the spectacle when the original photograph was taken. Former attempts to associate a gramophone with the cinematograph film have failed from lack of synchronism, which has sometimes given absurd results, but in this case perfect correspondence is assured because the sound record is taken actually on the moving film itself. When the picture is being exposed the sound waves are converted into minute varying electrical currents, which again are transformed, by a light-sensitive cell, into light, the actinic properties of which vary with the strength of the currents. This light is made to impress itself through a slit upon the border of the film as it winds through the camera, and gives the film the appearance of being edged by a series of horizontal lines, perhaps 500 to the inch, varying in gradation according to the incident light. On projection the same process is used backwards, the light, fluctuating according to the density of these lines, is reconverted into varying electrical currents, which are made to operate the diaphragm of a "loud speaker," and thus a perfect record of the original sound reaches the ears of the audience at the same time as the picture moves before their eyes. That, of course, is a very summary description of the process, which employs microphonic and other devices to get the registration of the sound and its reproduction in suitable volume. At the demonstration at the Royal Society of Medicine the President of the United States came into the picture, full length, and proceeded to deliver an oration—a most uninspiring performance, by the way—in which his lip movements and gestures were in perfect accord with the words he was uttering as transmitted by the "loud speaker." Dr Heald instanced the various directions in medical education in which this invention may be of value. He thought it might be applied to the reproduction of clinical lectures to students or post-graduates, the illustrative cases could be well shown on the film, thereby avoiding the transport of patients. Demonstrations in dissection by well known anatomists, experiments on animals seldom seen by the student, special or rare operations by distinguished surgeons, new techniques in diagnosis or treatment, might be described, and, of course, the record once obtained, it could be used any number of times for further reference and could be sent from place to place. Indeed, a "talking film," produced so expeditiously, might conceivably take

the place of ordinary reports of lectures and discussions. A time might come when, instead of columns of unaltered type recording the proceedings of the House of Commons, or even some other public assembly, a "talking film" will be taken and multiplied and sent into the country, where the constituents can sit in judgement, not only upon the words, but upon the style and demeanour and impressiveness of their representatives. Such a record, while more lively and human than printer's type, and impregnable to complaints of misreporting or misdescription, would have the drawback of deadly accuracy, it would show no mercy, present no kind omission or condensation, and would be powerless to dignify or clarify the phraseology. The "talking film" would render the stark reality of what the speaker said, instead of giving what he would have liked to say, or what he thought he did say (which often comes to the same thing). A less ambitious application of the cinematograph in medicine was demonstrated at the same meeting, when Dr L. D. Bailey, by the courtesy of Sir Charles Ballance and Mr. Colledge, exhibited a number of films illustrating recovery of function, as determined by electrical reactions and by voluntary movements, after nerve anastomosis. The records showed the results obtained in monkeys some months after nerve transplantation, and also in human subjects who had been treated for facial paralysis by the transplantation of the hypoglossal nerve into the facial, and the descendens noni into the distal end of the hypoglossal. Although the records did not bring out all that the producer wished, particularly in the difficult monkey subjects, they were very successful for what was believed to be the first occasion on which a cinematograph record of radiographic response has been secured.

RADIOLOGICAL DAYS

THE British Institute of Radiology has arranged to have once a month during the session a radiological day, for the benefit in particular of provincial members. The day selected is that on which in the evening the Electro-Therapeutics Section of the Royal Society of Medicine meets. On the afternoon of that day a demonstration will be given at one of the London hospitals, and in the evening of the day before there will be a meeting at the Institute (32, Welbeck Street) for informal conversation and consultation. The first of these, which was held last week (November 19th), was well attended by London and provincial members. Many interesting radiographs were shown, including a number lent by the Mayo Clinic, and others were brought for diagnosis and discussion by those present. The demonstration on the following afternoon was given at the London Hospital by Dr Gilbert Scott, whose subject was gastric radiology.

WE regret to announce the death on November 23rd, at the age of 89, of Sir R. Charles Brown, M.A., M.B., F.R.C.P., F.R.C.S., of Preston, a magnificent benefactor of medical research and medical charities. We hope to publish a memoir in our next issue.

IN accordance with a resolution of the Lambeth Conference of 1920 that much good might be done by the appointment of a permanent committee of clergy and doctors to advise the authorities of the Church on these matters, a committee has now been set up. The medical members are Dr William Brown, Wilde Reader in Mental Philosophy, University of Oxford, Dr H. C. Cameron, physician to Guy's Hospital, Dr J. Walter Carr, consulting physician to the Royal Free Hospital, Mr W. McAdam Eccles, surgeon to St Bartholomew's Hospital, Sir Percival Hartley, physician to St Bartholomew's Hospital, and Sir Maurice Craig, physician for psychological medicine Guy's Hospital. The clerical members are the Bishop of Southwark (Dr C. F. Garbett), who will act as chairman of the committee, the Dean of St Paul's (Dr W. R. Inge), Canon T. W. Pym, Head of Cambridge House, Cumberwell, the Rev. T. Underhill, the Rev. Harold Anson, and the Rev. L. W. Grensted.

An Address ON POST-GRADUATE MEDICAL EDUCATION IN ENGLAND.

DELIVERED BEFORE THE MANCHESTER MEDICAL SOCIETY
BY

SIR HOLBURN J. WARING, M.S., F.R.C.S.,
SURGEON TO ST. BARTHOLOMEW'S HOSPITAL

POST-GRADUATE education in England from the medical graduate's point of view is very unsatisfactory. The clinical opportunities available in London, and in some of the large provincial centres, Manchester especially, are unequalled. In London post-graduate medical education is carried on by (1) the Fellowship of Medicine and Post-Graduate Medical Association, (2) intensive and revision courses held at the undergraduate medical schools, (3) clinical assistantships, and other short period clinical posts in hospitals, either with undergraduate medical schools or non-teaching hospitals, (4) courses on tropical medicine and hygiene at the London School of Hygiene and Tropical Medicine.

1 *The Fellowship of Medicine and Post-Graduate Medical Association*

This body is in the main an association of teachers of medicine who have made arrangements with a number of the undergraduate hospitals and medical schools and a large number of the non-teaching hospitals, general and special, to give them clinical facilities.

This Fellowship of Medicine and Post-Graduate Medical Association has for its administrative quarters a small amount of accommodation—one room on the top floor—in the Royal Society of Medicine's house at 1, Wimpole Street. The permanent administrative staff, as far as I am aware, consists of (1) a lady, who devotes the whole of her time to the duties, and is assisted by a lady clerk, and (2) two honorary secretaries, medical men attached to non-teaching hospitals, who devote a small amount of time to its organization. The administrative body is a large committee or council, consisting of 112 members, and an executive committee. The executive committee down to this year consisted of twenty members, but this year the number has, I understand, been reduced to seven. Practically all the work of the Post-Graduate Association, however, as regards its administrative dealings with students, is carried on by the lady clerk or secretary and her assistant.

The constitution of the Fellowship of Medicine and the Post-Graduate Medical Association (which were originally separate bodies, but were united in 1919) is a loose one, since it is not incorporated by royal charter as a corporate institution, or by registration as a similar body under the Companies Acts. One result of this loose constitution and the exceedingly poor administrative organization, in my opinion, has been the greatly delayed further development of post-graduate medical education in London. For a considerable period I was a member of the General Council of this body as the representative of the Faculty of Medicine of the University of London, and consequently had a good opportunity of observing some aspects of the working. The inner workings of the executive committee, however, I was never intimately acquainted with, as I was never elected as a member of that body.

This Fellowship of Medicine and Post-Graduate Medical Association has been in existence in its present form for about six years. Before that there existed two bodies—(1) the London Post-Graduate Association, or School of Medicine, founded in 1917, and (2) the Fellowship of Medicine, founded in 1918. A post-graduate teaching body, at one time called the Polytechnic, existed in one form or another from its commencement by the late Sir Jonathan Hutchinson at his Clinical Museum until the early part of the war. A study of the prospectus of this Fellowship of Medicine and Post-Graduate Medical Association shows that at the present time there are seven undergraduate hospitals and schools and forty-two non-teaching general

and special hospitals taking part in its activities. The total teaching staff would appear to be several hundreds. The number of students who took advantage of the courses provided by the Fellowship of Medicine and Post-Graduate Medical Association during the past year was 399.

The facilities provided are either general or special, and consist of (a) admission to the clinical practice of the various hospitals, (b) periodical regular intensive courses in general and special subjects of limited duration, of two, three, or four weeks, as the case may be, and (c) special lectures in different branches of medicine. These latter are given at individual hospitals or schools, or at the rooms of the Royal Society of Medicine. In many cases, the lectures consist of clinical demonstrations of select and rare clinical cases.

The loose organization of this body and the large number of places available for instruction has made it difficult for a prospective post-graduate student to decide how to obtain the instruction in clinical practice which he requires. Instruction in the basic scientific subjects of medicine in the main has only been available at the undergraduate schools. One result of the large and indiscriminate number of places of post-graduate medical study available has been that, in comparison with the receipts, the expenses of carrying on the work of the Fellowship of Medicine and the Post-Graduate Medical Association are very considerable, and there have been practically no funds to remunerate those teachers who have taken part in the courses of instruction. The 1924 balance sheet shows that approximately £2,668 was received as fees from students and payment for courses. Of this amount £1,505 was paid to the hospitals as remuneration for teaching services and for expenses.

In my opinion the main causes of the comparative failure of the Fellowship of Medicine and Post-Graduate Medical Association are the non-corporate existence of the body, its non-association with a supreme medical body, such as the University of London or the Royal Colleges of Physicians and Surgeons, the lack of a centrally situated general hospital of sufficient size and entirely devoted to post-graduate medical instruction, and the absence of a central administrative building under the control of a medical post-graduate dean, with an appropriate administrative staff.

2 *Intensive and Revision Courses held at the Undergraduate Medical Schools*

Many of the undergraduate medical schools in London provide an intensive and revision course of two or three weeks' duration once a year, usually in the long vacation, for post-graduate students. In the main these courses have been intended for the old students of the school concerned, and to them has been given priority as regards entry. Within certain limits these courses have been comparatively successful. They do not, however, meet the main wants of post-graduate medical education, and are only suitable for intensive revision by general practitioners, but not for advancement of knowledge and increased experience in special subjects.

3 *Clinical Assistantships and other Short Period Clinical Posts in Hospitals*

A considerable number of these posts have been created and are available in the hospitals attached to the undergraduate schools. In the main they are open able to members of the undergraduate school or to post-graduate medical students from elsewhere when the students of the undergraduate school are insufficient to fill them. In many instances absence of regular courses of instruction, in connexion with these clinical posts or appointments has diminished their value, and post-graduate medical students also have not been attracted owing to the fact that they have to work on equal terms with undergraduate students. In practice, in my experience, it has always been found that a mixture of undergraduate and post-graduate students in medicine for teaching purposes is unsatisfactory. They do not work well together. The undergraduate distrusts the post-graduate student and looks upon him as an intruder, whilst the post-graduate student objects to working with and being classed along with the undergraduate. Until recently separate post-graduate courses of medical

instruction were carried out at certain non-teaching hospitals (a) the Seamen's Hospital, Greenwich, (b) the West London Hospital, (c) the Royal Northern Hospital, and (d) the Prince of Wales's General Hospital at Tottenham.

During the war all these courses of instruction were discontinued, and since then they have in the main become almost entirely merged in the Fellowship of Medicine and Post-Graduate Medical Association. I believe, however, that the Seamen's Hospital still gives a course of instruction in operative surgery on the dead body. This is possible for that institution, owing to the fairly large amount of material which is available for the purpose. It would appear, however, that the courses held there are open both to undergraduates and graduates, but they are mainly made use of by graduates preparing for university examinations, or by candidates for the Fellowship of the Royal College of Surgeons of England. The Prince of Wales's Hospital at Tottenham and the West London Hospital at Hammersmith have still post graduate medical schools.

The groups which I have enumerated comprise, as far as I know, all the fixed courses of post-graduate instruction in medicine in London.

As regards the success of the courses, it appears from the balance sheet of the Fellowship of Medicine and Post-Graduate Medical Association that during the year 1924 the total receipts amounted to £1,565 14s 10d in respect of fees from post-graduates, and £1,102 9s 3d in respect of courses. The total income of the Fellowship of Medicine and Post-Graduate Medical Association in 1924 was £2,872 14s, of which £2,668 was provided by fees in respect of students and for courses, £133 6s 8d by subscriptions, £3 2s by donations, and the remainder was invested on bank deposits and funding loan bonds. The total expenses apparently were £220 8s 4d less than the total receipts. The amounts which were paid for the payment of hospitals in respect of courses, and expenses in connection with them was £1,505. This amount, I assume from the statements in the balance sheet, includes the fees paid to lecturers and others who took part in the instruction.

This statement seems to prove that as at present arranged the post-graduate instruction in London is not a great success, and may be regarded as a failure, since the number of hospitals taking part in the course is forty-nine and the number of teachers apparently several hundreds.

4 Tropical Medicine and Hygiene

The London School of Tropical Medicine and Hygiene has given regular courses of instruction with clinical work for a number of years. At first these were carried on at the Branch Hospital of the Seamen's Hospital at the Albert Dock, and more recently at the School of Tropical Medicine in Endsleigh Gardens. This school has been taken over and is now carried on by the London School of Hygiene and Tropical Medicine recently constituted by Royal Charter. This was rendered possible by the munificent gift of the Rockefeller Trustees of 2,000,000 dollars and the promise of an annual grant of £25,000 from the Government towards its maintenance. This school is very flourishing, and is an example of what a post-graduate medical school ought to run at.

In the provinces some of the medical schools—Manchester, Liverpool, Newcastle, Bristol, Birmingham—give instruction in post-graduate subjects by means of lectures at stated intervals, and occasionally, I believe, by short intensive revision courses. Otherwise there does not appear to be any further systematic instruction in the provincial schools, with the exception of Liverpool, where there is an excellent school of tropical medicine. There are, however, in some of them clinical assistantships and resident posts similar to those in London. In some of the large medical centres a system of post-graduate education by means of lectures and demonstrations has been arranged by the local Branches of the British Medical Association. These, however, are limited, I understand, to members of the Association, and cannot be looked upon in any wise as regular courses of post-graduate medical instruction. The Liverpool School

of Tropical Medicine provides an excellent course of instruction and clinical facilities in tropical medicine.

At the commencement of the union of the Fellowship of Medicine and the Post-Graduate Medical Association apparently all the undergraduate schools in London took part in the combination. Since then, however, owing to the non-success of the arrangements, and the unsatisfactory results from the combination of instruction of undergraduates and post-graduates together, several of the schools, such as St. Bartholomew's, Guy's, University College Hospital, and Middlesex, now take no part in the association.

As regards fees, the fees charged by the association for courses of instruction in March, 1925, were One week, £2 2s, two weeks, £3 3s, one month, £5 5s, two months, £9 9s, three months, £12 12s, six months, £18 18s, one year, £21. These fees entitle the holder of the ticket to attendance at all the hospitals comprised within the combination, and upon most of the special courses held during the period of the validity of the ticket. Certain special courses, however, were excepted, and for attendance on these special fees were necessary.

I think I may state that without exception it is impossible to carry on satisfactorily any form of scientific instruction, such as is necessary in medicine, on fees which are paid by the student alone. It has been found in practice that in order to carry on successfully courses of instruction in medicine the minimum which can be expected for fees should not be more than 50 per cent and probably 33 per cent. This fact, in my opinion, in addition to those I have already mentioned, is one of the main causes of the failure of post-graduate medical education in London and the provinces. One result of the non payment of teachers giving instruction in medicine is that the attendance of the teachers is liable to be irregular, and also there is a great temptation for the instruction to be in the main an advertisement of the lecturer.

At the present stage I should like to refer to an aspect of post-graduate medical education which is an important one. In the past the medical department of the navy and the medical department of the army have been accustomed to make arrangements with certain metropolitan medical schools for the carrying out of a course of instruction to batches of officers in the Naval Medical Service or in the Army Medical Service. In my opinion the method of instruction given in these cases has not been of the right kind. Each batch, or class, has been allotted to one or two members of a hospital staff, who have given them instruction at stated periods. The instruction has merely been of the type of class demonstration or lecture. This is not sufficient for members of the Naval Medical Service or the Army Medical Service, who may not have had any practical dealings with patients for extended periods. Such men ought to be given definite clinical posts in hospitals, to which posts are attached the care and treatment of patients.

Post Graduate Medical Education in England as it should be

In my opinion it is essential, in the arrangement of post-graduate courses of instruction in medicine, that each centre should be first of all under the direct control of some body, such as a university, or in London the Royal Colleges of Physicians and Surgeons. Each school or faculty of post-graduate instruction should have its own organizing dean and administrative staff, with separate administrative offices and separate general and special hospitals and scientific laboratories.

In the case of London, which is a special one, I think the best course to pursue would be to create a post-graduate medical college or school, which should be a school of the University of London. This school, or college, should have (1) administrative offices, the staff of which should consist of a whole-time dean of the post-graduate medical college and requisite clerical assistance, the dean, in my opinion, should have had a medical education and also training in the administration and organization of medical education, (2) a general hospital of at least three to four hundred beds, which should be centrally situated, and, if possible, the administrative office and the school should be located in close proximity to, or in the buildings of, this hospital. If the hospital contained 400 beds the beds might be

allocated 100 to general medicine, 100 to general surgery, 50 to gynaecology, and the remainder divided between the special departments. One hundred beds allocated to general medicine and general surgery respectively would allow for the formation of two clinical units in each division, and one unit in obstetrics and gynaecology. The number of beds allocated to the other special branches might vary according to the possibilities of making use of large special hospitals. In connexion with the staff in medicine and surgery and obstetrics and gynaecology, in my opinion, one unit in medicine, one in surgery, and one in obstetrics and gynaecology, ought to be under the direction and in charge of a university professor. This university professor should have general charge of the administration of the whole of the beds allocated to his subject, but the second and possibly third units in medicine and surgery, although from an administrative point of view under his general direction as regards teaching facilities of the professor, would be otherwise quite separate and distinct.

As to whether the university professors in charge of these units should be whole-time posts or not is a matter of opinion. In London for the past five years the system of the whole-time professor in medicine and surgery, and in one case midwifery, has been on trial. In the main, I think the units have been satisfactory, perhaps more so in medicine than in surgery. They have generally increased the level of teaching and instruction in a school by first of all improving the teaching, etc., in the professorial unit and thus has reacted on the non-professional units and so brought them more or less to a similar higher level. The special type of man who is suitable for appointment to one of these posts is not easily found. Each professor of a clinical subject in medicine is expected to be (a) an authority in his special part of medicine, (b) a good teacher and lecturer in his subject, (c) a good clinician, and, in the case of surgery and gynaecology, a good operator, (d) a good organizer and administrator, (e) a good researcher or director of research, and (f) a presentable man of the world who is capable of dealing satisfactorily with and meeting on their own level all kinds of men and women authorities in his own special subject. It will be seen from this that the ideal professor in the clinical subjects requires to be an extremely capable man, well versed in every branch of his subject. In the past it has been found difficult to obtain for these posts candidates who possess all the qualities which are desirable. This in part is due to the fact that such combinations are rare to find in the same individual, and the pecuniary attractions of the posts in the past have not been sufficient to attract the most suitable candidates.

Concerning the provision of a special general hospital in London allocated for post-graduates' medical education it is essential that the hospital should be in a central position and readily accessible from all parts. At the present time there are twelve general hospitals to which undergraduate medical schools are attached. In my opinion this number is far too great, and the most sensible and practical method would be to detach one or two of these hospitals from undergraduate medical instruction and to turn them into post-graduate hospitals and schools. In theory this might sound to be quite an easy matter, in practice, however, it has been found very difficult.

During the period when I was Vice-Chancellor of the University of London I made a serious attempt to establish a post-graduate school commencing on these lines. I found, however, in discussing the matter with the authorities of the schools, that there were no schools which were willing to fall in with such a scheme. From the negotiations which took place, and in which I took part, it seemed to me that one of the main causes of the extreme reluctance of one or more of the present undergraduate schools to become entirely a post-graduate school was either the insufficient financial aid which the university could primarily offer, or the disinclination of the school to make a change. There is one factor, however, in connexion with the constitution of the medical schools in London which makes it difficult for them to deal with a matter of this kind. In the main each medical school is governed by a committee of the medical staff of the hospital, in some cases supple-

mented by additional members from the lay governing body. The individual schools in the main have no separate corporate existence, with the exception of the Medical College of St. Bartholomew's Hospital, and the Medical School of University College Hospital, and it is necessary when dealing with Government departments, or large institutions, such as the University of London or the College of Physicians and Surgeons, for negotiations to be carried through secondarily by the governing body or committee of the hospital, the composition of which is chiefly lay in character. This reluctance on the part of the present undergraduate hospitals, and the unsuitability of any of the existing non-teaching hospitals, may necessitate the establishment of a new hospital for the purpose. It does not appear to me that any of the present non-teaching hospitals in London are suitable for establishing in them a central post-graduate clinical school such as is required. This unsuitability is due in the main either to the insufficient size and accommodation of the hospital or to its inaccessible and non-central position.

When the central hospital has been established, with it there ought to be associated a number of large special hospitals. I would include amongst these the following:

Ophthalmic—Moorfields, Westminster Ophthalmic Hospital, Central London Ophthalmic Hospital, and possibly the South London Ophthalmic Hospital.

Midwifery and Gynaecology—Hospital which might be used for this purpose are the Samaritan Hospital for Women, Queen Charlotte's Maternity Hospital, York Road, Living in Hospital, Royal Waterloo Hospital for Children and Women.

Orthopaedic—Royal National Orthopaedic Hospital.

Oto Rhino Laryngology—Hospital for Diseases of the Throat, Golden Square, Hospital for Diseases of the Ear, Great Inn Field, Hospital for Diseases of the Ear, St. John's.

Children's Diseases—Hospital for Sick Children, Great Ormond Street, Hospital for Sick Children, Paddington Green, and the Evelina Hospital for Sick Children, Shadwell.

Diseases of the Nervous System—National Hospital for the Paralysed and Epileptic, Queen Square, and the Maudsley Hospital.

In order to make all these special hospitals suitable for teaching and for carrying on post-graduate medical education it would be necessary in many instances for the hospitals to improve their pathological and scientific facilities. This, however, ought not to be a difficult matter, since if a real first class post-graduate school were established on the lines indicated, all that would be necessary would be for the central governing body of the school to make it a condition for hospitals entering into such a post-graduate scheme to equip themselves in a first-class manner and bring their pathological and scientific departments up to date. In addition to provision of a general hospital with its associated special hospitals, it would be necessary to have laboratories devoted to the various branches of pathology, which would be available for post-graduate students. If one of the existing medical schools were utilized, the laboratories in connexion with the school selected might possibly, with additions, meet the case.

Public Health and Hygiene

This special subject, essentially a post-graduate one, is now on the way to a satisfactory solution in London. By the munificence of the Rockefeller Trustees the London School of Hygiene and Tropical Medicine, a school of the University of London, has been founded. A site has been obtained in a central position between University College and the British Museum, and the building will soon be erected. The site has cost a little over £50,000, and about £375,000 is to be expended on the building. From the plans of the building, which I have seen, and the plans of organization now being evolved, I have little hesitation in asserting that this School of Hygiene and Tropical Medicine will be second to none in the world.

I hear that plans are being evolved for the possible establishment of an institute of forensic medicine on extensive lines. The establishment of such an institute is essential if London is to maintain its position as one of the great centres of medical education.

In association with the central hospital it would be a great advantage to have the clinical facilities of some of the Poor Law infirmaries and hospitals of the Metropolitan Asylums Board available, since in these institutions many

varieties of disease, especially chronic diseases, can be studied, which cannot readily be met with in the ordinary general hospital. In the past it has not been an easy matter to make arrangements of this kind with the Poor Law infirmaries, since these institutions are under the control of boards of guardians, who appoint their own medical staff, and they do not like to be in any way interfered with by the authorities of a teaching school. I have no doubt, however, that if a post-graduate school were established, with a proper government and as part of a big university system, such difficulties could readily be overcome.

When a post-graduate medical school has been established on the lines which I have indicated it will be a great advantage to have in close proximity to the central hospital and the administrative offices a residential hostel where post-graduate students might live a more or less temporary collegiate life.

Such is an outline of what I suggest as the best provision for post-graduate medical teaching in London.

As regards the provinces, I think certain centres might have a post-graduate school established on the lines I have already indicated in connexion with London. I know of no other place in the provinces where a school could be established with greater advantage than in Manchester. Here you have a university in the centre of an area of population as large almost as that of the metropolis, attached to which is a complete undergraduate medical school. If a post-graduate medical school were established entirely distinct in its organization and detached administration from the undergraduate one, I think it ought to be a great success, and possibly an example of what could be done in other places. I understand that there are here two large general hospitals distinct from the general hospital attached to the undergraduate school, and also a number of special hospitals which might be utilized in a similar way.

Staffing of a Post-Graduate Hospital

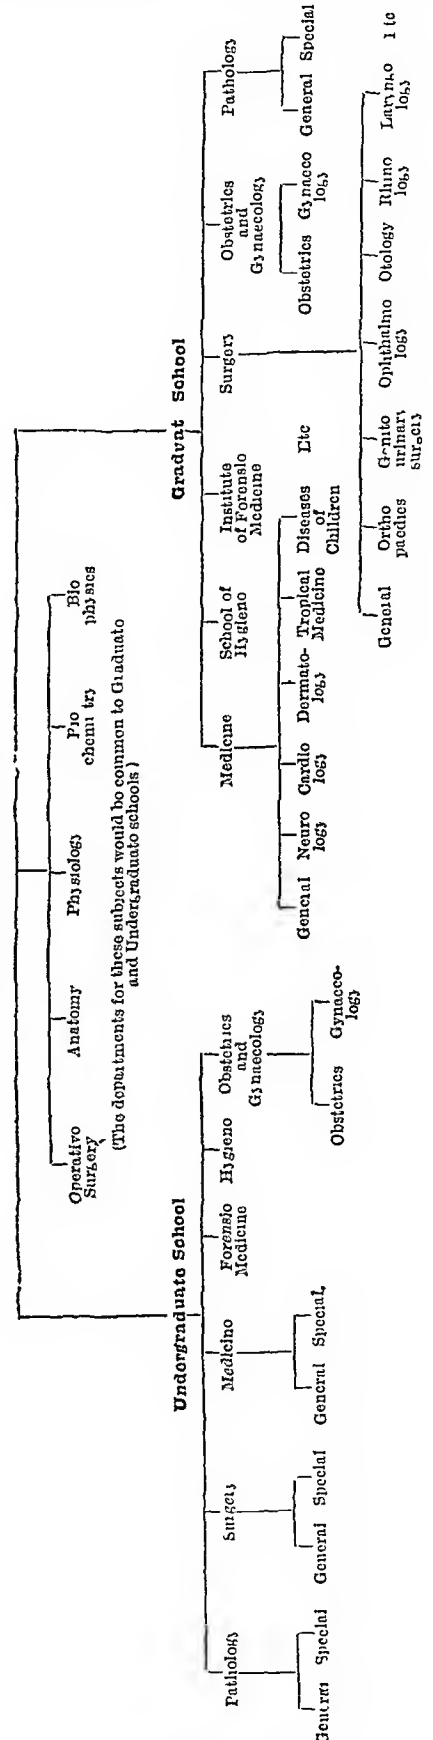

There is one point of very great importance in the establishment of a post-graduate school of medicine which still requires serious consideration, and which in my opinion will present numerous difficulties: this is the selection, arrangement, and appointment of a suitable staff for the newly established post-graduate hospital. From this point of view I have little doubt that the easiest and best method of procedure would be to erect an entirely new hospital, the staff of which could be completely organized on a definite post-graduate teaching plan. The great objection to erecting such a hospital is the question of expense. Since, however, it is so very essential for the good of the community and for the retention and improvement of the position of London as one of the important medical teaching centres of the world, I think this ought to be done if it is not possible to utilize one or more of the undergraduate schools. If such a plan is decided upon, it would not be difficult to find a central site suitable for the purpose upon which could be erected (a) a post-graduate hospital, (b) associated scientific laboratories, (c) administrative buildings, and (d) a hostel for the residence of students. A portion of the site now occupied by the Foundling Hospital, which has recently been sold, and is, I understand, available, might be considered.

In connexion with the permanent staff of the post-graduate hospital it might be an advantage to arrange that one or more units should not have a permanent clinical head allocated to them, but should be available for utilization by authorities and specialists in special subjects from other hospitals. Such teachers might be seconded for a session or period from their parent hospital in order to give advanced courses of instruction in their special subjects in the post-graduate school. An idea of this kind, I think, was in the mind of those who drafted the report of the Athlone Commission on Post-Graduate Medical Education in London. The size of a unit of this kind need not be more than twenty or twenty-five beds. Probably two units of this size—one medical and one surgical—would suffice.

SCHEME FOR A COMPLETE FACULTY OF MEDICINE

UNIVERSITY OF X

FACULTY OF MEDICINE

Finance

If a scheme of this kind is finally adopted it will be necessary that a considerable sum of money should be provided, either from public funds or from large private benefactions, for upkeep of the school and maintenance of the hospital. As regards the amount of money required, it is essential in estimating this that provision be made for the payment of a dean and administrative staff, reasonable payment for those teachers who take part in the various courses, also for the proper payment of any full-time university professorships which may be tenable in the school.

One of the constant aims in the organization of the courses of instruction in the post-graduate medical school ought to be regular courses of practical instruction associated with and followed by clinical appointments which involve the examination of patients and their treatment. This is a part of post-graduate medical education which has been very neglected in the past. This is due, to a great extent, to the lack of laboratory facilities and the personnel for teaching. The provision of courses of this kind is essential if the best type of our own graduates, and also graduates from the colonies and other countries, are to be attracted to the post-graduate schools. Some people have objected to making the post-graduate schools a source of attraction to colonial, and especially to foreign, students. With this view I strongly disagree, as I think that if our position is to be maintained, and, if possible, enhanced, is a sort of advanced medical learning, then we must have colonial and foreign students who will carry back to their countries of origin an account of our resources and our reputation.

In connexion with the medical branches of our combatant services a certain proportion of the resident staff appointments and clinical assistantships ought always to be available for members of these services. If a post-graduate school on the lines mentioned is established it ought to be the centre of post-graduate clinical medical instruction for members of the medical services of the Army, the Navy, and the Air Force. It is only by the provision of facilities such as have already been detailed that one may expect that the members of these medical services shall be able periodically to revise their knowledge and bring it up to date. No method of revision courses such as is at present practised in our general hospitals, mainly by lecture and class demonstration, is sufficient for the purpose. Full provision ought also to be made for carrying out research in the various branches of medicine.

In connexion with post-graduate medical education there is one point which, so far as I know, has not yet been touched upon. This is the post-graduate education of nurses. The nursing profession is a most important adjunct in carrying on successfully diagnosis and treatment of disease. This being so, it seems logical and natural that nurses should have facilities provided for them where they can undergo post-graduate education on the lines similar to those in connexion with the medical practitioner.

I have not yet dealt with one aspect of the problem which, in my opinion, is of considerable importance—this is, what process of "hall-marking" shall be adopted by the post-graduate medical school, or the university to which it belongs, after a satisfactory course of instruction has been attended? For students who attend special courses for short periods, say up to one year, the present diploma in special subjects of the Royal Colleges of Physicians and Surgeons and of some of the universities would probably be sufficient. If, however, a student should devote, say, three years to a continuous course of post-graduate medical education it might be advisable to give him, in the case of a university, some form of special degree. This might be either a Doctor of Philosophy, or a Doctor, or Bachelor, or Master of Medical Science. In any case, such a degree ought not to be a registrable one. On general principles I should not be in favour of the granting of a degree of this kind. There are, however, undoubtedly many instances where the granting of such a degree would be justifiable and advisable. In the case of special subjects, such as ophthalmology and oto-rhino-laryngology, diplomas are already granted.

A Post Graduate Medical Education Committee has been

appointed recently by the Minister of Health to draw up a practicable scheme of post-graduate education in London, taking account of the needs of the medical profession of this country and of the members of the profession visiting this country from overseas. The immediate questions to be answered by this Committee are:

1 Is there agreement as to the absolute necessity of a reorganization of post-graduate teaching?

2 Is there agreement on the general recommendations of the Athlone Commission?

3 Is there agreement that such recommendations can only be realized by new buildings? or could the recommendations be reasonably carried out by some method of adaptation of existing hospitals or medical schools?

It may be remembered that the Athlone recommendations suggested the following scheme:

(a) A bureau or clearing-house for all applicants for post-graduate facilities [This might suitably be at the British Medical Association offices].

(b) A residential hostel and social centre.

(c) A college, with laboratories, etc.

(d) A modern hospital, fully equipped [100 to 250 beds].

The hospital and college should be in the same building.

(e) Full co-ordination with other hospitals in London and the provinces, in order to provide for the teaching of special subjects and the accommodation of English post-graduates who cannot come up to London.

THE ROYAL SOCIETY OF MEDICINE

ANNUAL DINNER

The annual dinner of the Royal Society of Medicine took place on November 19th, when a company of close upon four hundred gathered at the Hotel Victoria, and Sir StCLAIR THOMSON presided with his customary geniality. Among the principal guests were:

The Right Hon. Neville Chamberlain (Minister of Health), Sir Arthur Robinson (First Secretary of the Ministry), Sir Robert Philip, Dr. R. A. Bolam (Chairman of Council of the British Medical Association), Sir Holburt Waring (President, Medical Society of London), Dr. Vincent Dickinson (Master, Society of Apothecaries), Dr. Howard Humphris (President, Hunterian Society), Sir John Broadbent (President, Harveian Society), Dr. P. Seymour Price (President, Chelsea Clinical Society), Dr. H. W. Aitstead (President, West London Medico-Chirurgical Society), Mr. Guy Dawber (President, Royal Institute of British Architects) and Sir Dawson Williams (Editor, *British Medical Journal*).

One of the ceremonies of the evening was the unveiling of a portrait of Sir John MacAlister, until recently secretary of the Society. The portrait, by Mr. Eric Kennington, shows Sir John in his prime, with his books and paper beside him, and the artist has not forgotten to depict the incense of tobacco smoke. The portrait is to be hung in a permanent place in the hall of the Society's house. The unveiling was performed by Miss Williamson, who was Sir John MacAlister's assistant for twenty years, and a brief acknowledgement was made by Mr. Donald MacAlister, who said that the greatest pleasure of his father's life was to be still in touch with the Society.

The MINISTER OF HEALTH, in proposing the toast of the Society, remarked on some contrasts between medical men and politicians. "Your results are based upon methods of precision, you draw your conclusions cautiously from fully proved premises, we, on the other hand, rush into any kind of rash experiment—so I am informed—with an ignorance which is only matched by our irresponsibility. You wait to give your services until they are asked for, we not only prescribe, but I read that we absolutely force our medicines down the throats of our unwilling victims. You practise what you preach, we 'try it on the dog,' and reserve our own liberty of action. You eschew advertisements, we seek the limelight. But there are similarities between us also. Both of us would agree that the public could not do without us short of irreparable disaster. Both of us would agree that the remuneration we receive for our services is totally inadequate. And I rather think that both of us would say with regret that there are members of our professions whose views and whose practices can only be called deplorable."

(Laughter) Mr Chamberlain went on to speak of the Society, which, as the Medical and Chirurgical Society, was founded in a tavern about 120 years ago. It had gone on from very small beginnings to a Society of 4,000 Fellows, 24 Sections, and an income of £20,000 a year. It was a little unfortunate that the foundation of the Ministry of Health should have coincided with a period of housing shortage which made it appear that the Ministry devoted its energies almost entirely to this one subject—a subject which, of course, had a very important bearing on health, but was not what was in the minds of those who originated the Ministry. But although the Ministry had had this "euchronia in the nest," he wanted it to be believed that the Ministry had never ceased to devote thought and energy to the problems in which the medical men around him were interested, and now that houses were being built at the rate of 160,000 a year he thought the Ministry would be able to give more attention to other great problems of health. There was a project for which he would like to bespeak the goodwill of the Society. It was only a project at present under consideration by the Ministry, but it was one which he earnestly desired, before he left his present office, to put into practical operation, or at least to see carried so far that its future success was assured. The project was the establishment of a post-graduate school in London. This was no new idea, many valiant efforts had been made in this direction in the past, but he thought that with co-operation between the profession and the Ministry of Health, and with the goodwill of colleagues overseas, it might be possible to place this matter on a new footing. The problem was bristling with difficulties, but he believed that with determination and mutual confidence the difficulties could be surmounted. He had already been able to secure the assistance of a number of very representative physicians and surgeons who had consented to serve on a committee over which he was going to preside. Preliminary meetings only had been held, and owing to the intervention of the holiday season no very great progress had been made, but the committee would soon be setting to work again, and he trusted that in the course of the next year or so they might all be able to congratulate themselves upon the fulfilment of their desires. The Ministry was responsible for the system of national health insurance, which employed the services of great numbers of medical practitioners, and he could not help thinking that if a post-graduate school were established to which practitioners could have access it would do a great deal to maintain and even to raise the standard of their practice, with consequent benefit to their patients. (Applause)

Sir St. Clair Thomson, in responding, described the Society as a guild for the diffusion of knowledge in the science and art of medicine. The gold of this guild was dug up in daily practice, in the wards, and in the laboratories, it was also garnered from the progress of many neighbouring sciences, but at the Society it was tested, minted, and put into circulation. He paid a tribute to the retired secretary, mentioning that in 1887, when Sir John MacAlister began his reign, there were 745 Fellows, and the yearly proceedings of the Society were contained in two handy volumes, produced at a cost of £400. Today the number of Fellows was 4,000, and the *Proceedings* ran to 1,200 pages, cost £4,000 a year, and were big and heavy enough to be used for pressing trousers. (Laughter) During the last session the Society and its Sections held 171 meetings, which were attended by 6,800 members, and the library was visited by more than 20,000 readers. During the interregnum consequent upon Sir John MacAlister's illness and retirement, the Society had drawn upon the services of its honorary secretaries, Mr. Girdling Ball and Dr. Lethaby Tidy (which had been given without stint), and also upon the ungrudging services of its staff. He welcomed the new secretary, Mr. Geoffrey Edwards, who had been selected by the Council from among 400 candidates, and already had gone far to justify the choice. But the Society was not prospering to such an extent that it wanted nothing more. He read in the *British Medical Journal* that the Carnegie Corporation and the Rockefeller Foundation between them had endowed the New York Academy of Medicine with £500,000. The American Academy was not

as old as the Royal Society of Medicine, and not more illustrious, it performed much the same functions, but this generous gift would now enable it to add to its undertakings a bureau of clinical information and a committee for post-graduate education. The Royal Society of Medicine was willing to take on these and similar enterprises if it was supplied with the means. If anyone had a spare half-million to invest, the Society could give good security and a guaranteed return in the advance of medicine and the promotion of public health.

Dr. R. A. BOLAN proposed the health of the guests, and in so doing with the toast the names of Sir Robert Philip and Mr. Guy Dawber referred gracefully to the work of them both—the one in the conquest of tuberculosis, and the other in the progress of domestic architecture. Sir ROBERT PHILIP, in reply, spoke of the pleasure with which Edinburgh would welcome the British Medical Association in 1927, when he hoped that members of the profession would attend in very large numbers, not on account of Edinburgh or Scotland, but because a tribute was then to be paid to Lister, the great revolutionist in surgery, and the apostle and exponent of preventive medicine, on the occasion of his centenary. Mr. GUY DAWBER added a few words, pointing out the similarities of architecture and medicine. At the present moment architecture had two distinguished "invalids"—Waterloo Bridge and St. Paul's. With regard to the latter, the doctors who had been called in entirely disagreed with those who had not. Those who had proposed a more drastic surgical operation had been turned down, and a course of manipulative treatment was being pursued in which injections were given under high pressure, and it was hoped that this would bring rest to the "patient."

Dr. JOHN C. McVAIL, President of the Epidemiological Section, introduced Dr. S. Monckton Copeman, F.R.S., epitomizing in a few happy sentences his services to scientific medicine, and the President then, on behalf of the Epidemiological Section, handed Dr. Copeman the Jenner Medal, thus adding Dr. Copeman's name to the five distinguished workers in public health—Sir W. H. Power, Professor Laveran, Sir Patrick Manson, Sir Shirley Murphy, and Dr. McVail—to whom this medal has been awarded since its institution in 1896.

THE HEALTH OF THE SCHOOL CHILD

(Continued from page 972)

THE first part of the Annual Report of the Chief Medical Officer of the Board of Education for 1924 dealt with the general aspects of the school medical service. Of this we gave an account in our last week's issue. Following thereon are a series of reports on special subjects or conditions that affect school children. The first of these deals with a subject of great importance, and it is worth while giving somewhat extended account of this section of the report.

THE HEALTH OF THE RURAL CHILD

The population of rural England and Wales accounts for one fifth of the total. Of the rural population one sixth, or 1,500,000, are children. Any scheme of national welfare must therefore include the right enjoyment of health for them equally with those who dwell in the towns. The community cannot afford to allow the country districts to be impoverished for in them is a source of national strength. The birth rate for the rural districts does not differ materially from the rate for England and Wales as a whole, nor, indeed, from the rates which obtain in urban areas. The same is roughly true of the death rate, and consequently of the rate of natural increase of population. That is to say, the countryside is providing its due proportion of increase of population. An examination of the returns from certain selected areas, however, reveals sharp differences. The natural increase per 1,000 of population in Liverpool is as high as 11.0. No county attains a figure anything near this. Some of them fall very low—for example, East Sussex 2.8, Merioneth, 2.4, whilst Cardigan is actually minus 0.1. The explanation is no doubt to be found in the migration of the more vigorous and younger elements of the country stocks to the towns, and this

presents a problem which cannot be viewed without some apprehension in regard to the upkeep of the best physical stocks in the country. An inquiry was set on foot amongst the school medical officers with a view to securing specific information on the health of the rural children. Four questions were asked, and the answers to these are given. It is found that there is much variation in different parts of the county, yet there are some lessons of a general

QUESTION 1 *What is the percentage of children in these rural schools who are physically below standard?* The replies show that of nearly 10 000 children selected at random some 20 per cent are obviously defective in general physique. In the West Riding the figure was 39 in Merioneth 47 and in Radnorshire 54 per cent. The incidence of poor physique appears to have a maximum between the years of 6 and 11, after which it begins to fall. Its maximum is later than in towns. It seems as though the effect of exposure to bad conditions had delayed results.

QUESTION 2 *Is the amount of physical defect in any school or area in 1925 greater or less than that found in previous years?* One school medical officer of experience, Dr. Coikery of Devonshire, formed the opinion that the physical condition of the children in certain of his rural schools was definitely decadent and worse in 1924 and 1925 than in 1910 and subsequent pre-war years. Criticism of these statements has tended to verify them, particularly the reports from the school teachers. One of these writes: "During the twenty years I have spent in this district the decline in the physique of the inhabitants of the outlying villages has been most apparent." Another says: "In my opinion the poor houses, the very elementary sanitary conditions and the poor feeding have a lot to do with the production of C3 children who attend my school. The farmers' children are well fed and consequently healthy but some of the labourers' children never have a really well cooked dinner, but tea and bread. When I came to X I was surprised to find a greater percentage of pale-faced children than I had observed in the schools of Liverpool and Wigan." From other parts of the county reports were variable. In Kent eight representative rural schools were inquired into: two teachers stated there was no physical deterioration among the children and the other six believed that deterioration had occurred whereas Dr. Fox, one of the assistant medical officers who had been working in the county since 1908, was unable to recognize any definite change and the returns of heights and weights of both boys and girls bore out his statement. Similar returns from the other selected areas tended to the same effect.

QUESTION 3 *Is there any difference in physical impairment between the rural and the urban children of the county?* General conclusions from the analyses obtained are not admissible as the areas are few and selected. Yet for what they are worth these routine reports of the school medical officers support the belief in general superiority of physique of the country child as compared with the town child and this conclusion has received from year to year many confirmations.

QUESTION 4 *What are the principal causes of such impairment as exists?* The general answer to this is that the physical and mental character of the child is often an expression not of medical conditions and influences so much as of the economic state. In prosperous districts the children flourish, in depressed districts they suffer. The rural labourer is not advancing relatively with the urban worker. The abolition of apprenticeship and the "literary" character of elementary education are not conducive to a sufficient supply of labourers able to earn a remunerative wage to support themselves and their families. Hence the migration of the best labourers to the towns while the worst remain and are unable satisfactorily to provide for their children. Food is the chief and most important factor in determining the health and physique of the scholars. Its insufficiency is probably the cause of degeneration in certain areas. Dr. Davies of Anglesey writes: "One constantly finds that the youngest of the impoverished household is fat and plump during the early years of his life, but begins to fall off after the age of 6 or 7 years. It is the 'baby' and the 'pet' for the first years and receives all the fat bits and extra milk. It is ousted from this favoured position on the advent of the next baby. The long journey to school has been held to be injurious by some. Inquiry shows that provided the child is well fed at home and at school that there are no arrangements for drying clothes and that allowances are made for absences in bad weather the school journey is not injurious."

But there is evidence that in some areas the school fabric and equipment are bad—for example, inadequate playground provision, absence of water supply, cold classrooms, damp walls, imperfect cloak room, accommodation, absence of drying facilities, bad ventilation and lighting, overcrowding. Unfortunately the economic conditions are not rare. Lastly there is in many schools lack of accommodation or arrangements for the comfort of the child who brings his midday meal. In some there are no arrangements at all so that the children eat their food at the desks in cloak rooms, passages, porches or the playground. No attempt is made in many schools to make the meal a valuable opportunity for teaching good manners and habits. The facilities for warming food are poor. Sometimes a teacher or neighbour helps the little ones otherwise there is nothing but cold food and drink through the day which is trying in winter.

Conclusion

The general conclusion of the inquiry is this: "The village school should take its share with the town school in being, as in the eighteenth century, the nursery of

national character and efficiency. It should be re-established in the confidence of the people. No doubt many village schools are adequately fulfilling their function but many are not. The physical wellbeing of the children lags behind their mental training, though in truth the two are interdependent. The remarkable progress which has taken place in the towns is not being shared in the rural districts."

Recommendations

Certain recommendations are made. Medical officers should search out the subnormal children. Arrangements should be made for effective treatment. School attendance of children under 6 years of age should be discouraged if the distance from school is excessive. There should be a sufficient midday meal. Parents should be guided in the choice of this meal. There should be school management where the child can take the meal. Canteens may be desirable in some areas. There must be facilities for drying, wet boots and clothes. Sanitary schools must be made sanitary. There should be an extension of women institutes and of such other bodies as teach mothercraft, "of which there is much ignorance and some neglect."

(To be continued)

RESPONSIBILITY, LEGAL AND MEDICAL

At a meeting of the British Institute of Philosophical Studies on November 19th the subject of "Responsibility, legal and medical," was debated by Sir Travers Humphreys (Senior Treasury Counsel, Central Criminal Court) and Dr. William Brown (Wilde Reader in Mental Philosophy, University of Oxford). Mr. H. J. Lusk presided.

Criminal Responsibility: A Legal View

SIR TRAVERS HUMPHREYS said that there was only one respect in which the medical and legal professions were likely to differ—namely, as to criminal responsibility. The simple and logical principle upon which the common law was based with regard to the responsibility of a person for an act contrary to the law was that no one could be convicted of a crime unless the act was done intentionally. For example, a person would not be held responsible for a crime committed in a state of somnambulism or under hypnotic influence. A person was always excused for the consequences of his act, although it might have caused injury and suffering to others, if it was not a voluntary act. But it had been realized that the detection of such an individual might be necessary to prevent the repetition of such acts, and the practice had grown up of directing juries to return the special verdict, "Guilty, but insane," and the judges, perhaps without legal sanction, ordered the person to be detained that the state of his mind might be inquired into. This had been consolidated by statute, but the Trial of Lunatics Act, 1883, did not explain what was meant by "insane so as not to be responsible for his acts." A man might be insane in the sense of being certifiable as a lunatic, and yet might be responsible to the criminal law for his actions. In the Lunacy Act a lunatic was defined as "a person of unsound mind," but that explained nothing, because most persons were of unsound mind to a greater or lesser degree. The speaker felt a good deal of sympathy for the medical man who, in border line cases, had to decide whether a fellow creature should be kept in a lunatic asylum on certificate when the medical man had no better assistance than a vague definition of lunacy, but it was almost impossible to lay down any definition of what constituted insanity. For some years past it had been suggested that there ought to be a law that the person who was supposed to be suffering from an uncontrollable impulse should not be held responsible for his crime. This was not the law at present, and never had been, although recently a very bold member of the legal profession suggested in the Court of Criminal Appeal that the judge at the trial had misdirected the jury in not telling them that his client was suffering from an uncontrollable impulse and that it was their duty to find the special verdict. Whether it ought to be the law was, in the speaker's opinion, better left

an open question. If medical and scientific men differed from the law as it stood, and wished such special defence added, he thought they should go to Parliament instead of, either in the witness-box or out of it, making suggestions to judges. At the same time, he thought they would have difficulty in convincing the House of Commons, and that in practice it would not be at all easy to get evidence that a man was suffering from an uncontrollable impulse.

The Problem of Abnormal Conduct

Dr WILLIAM BROWN, who dealt with the subject in a more general way, referred to a suggestion that the modern doctrines of psychology tended to weaken the sense of moral responsibility. The truth was that psychology is such was not concerned with the central problem of responsibility at all, its task was to trace antecedent factors. Disordered conduct might be due to excessive strength of impulses needing control, or to exceptional weakness of controlling factors. Kleptomania was a familiar instance of this, or the impulse might be of a more serious nature and the patient might feel compelled to a murder or some other deed of violence. The psychological analysis of such cases often showed that events of early childhood were responsible for these impulses. Sometimes the responsibility lay more with those concerned with the person's upbringing than with the person himself. The question of irresponsibility in law got quickly mixed with insanity because it was only those who could be shown to be insane who escaped the application of the law. Insanity was a question of the degree of abnormality of a particular individual, and an attempt to make a scientific definition of insanity in regard to responsibility led at once to the domain of metaphysics. There were two extremes of thought, one that no person was responsible for anything but that everything was determined from birth (a difficulty which Aristotle countered by declaring that if the criminal said, "I cannot help doing this," society could say, "I cannot help punishing you"), and the other, that human beings were essentially free and responsible, though the responsibility might be diminished by disease. The problem of responsibility on the practical side was a question of the relation of the normal to the abnormal. The normal body politic developed its own laws corresponding with the normal individual who was expected to obey them. But there were people abnormal in various degrees, and the question was how the law could take account of that varying abnormality. It endeavoured to do so in regard to knowledge. If the individual did not know the nature and quality of his act that fact absolved him. With regard to uncontrollable impulse, the speaker was not sure that satisfactory objective evidence could not be obtained. If a man could show that he had been driven by some abnormal impulse for some time and had consulted a doctor, and the doctor could give evidence that treatment had been given, and that analysis had shown that the circumstances of his earlier years helped to explain his impulse, that should be sufficient evidence, and the person should escape punishment on the ground of uncontrollable impulse. The question remained as to whether justice could best be done by the law as it stood at present, or whether some modification was desirable. Dr Brown believed that the majority of medical men considered that the law ought to be altered in this sense, that some provision should be allowed for uncontrollable impulse. The sort of evidence that would be needed would be that revealed by deep analyses. It might be thought that this was the thin end of the wedge to get rid of responsibility altogether, but the more one understood the more one was likely to do justice. To realize the difficulties of the criminal or the patient did not mean that one thought less seriously of the crime. The sense of responsibility in that way would not be destroyed, but redistributed. Responsibility for a particular act by a particular person could generally be spread over a wide area, and it was only by allowing for multiple responsibility that the extreme position of denying responsibility altogether could be refused.

In some brief discussion, Dr T. B. HAYLOR said that a definition of sanity and insanity could not be given, any more than a definition of responsibility and irresponsibility.

He was wanting a legal definition of responsibility, insanity was a departure from such responsibility, and that seemed to be as far as they could go for practical purposes. Each case should be tried on its merits, and as in medicine they did not look up their archives in order to influence their judgement, so should it be in law.

England and Wales.

SHEFFIELD MEDICAL DINNER

THE Sheffield annual medical dinner was held at the Royal Victoria Hotel on November 12th. Dr A. C. Turner, D.S.O., chairman of the Sheffield Division of the British Medical Association, presided, and about 100 sat down at the tables. Mr H. S. Souttar, C.B.E., F.R.C.S., was the guest of honour. The function was one of the most enjoyable of its kind that has been held in Sheffield, and the success of the occasion was largely due to the honorary secretary of the Dinner Committee, Dr J. E. Stacey. The toast of "The City of Sheffield" was proposed by Professor C. J. Patten, M.D., in a speech brimful of Irish humour. The Master Cutler (Mr T. R. Elin), in reply, pointed out that the Sheffield Corporation only dated back to 1843, up to that time the Master Cutler had been responsible for the government of the city, previously they had had no Lord Mayor and no town councillors, but they seemed to have got on very well without them! Sheffield had been a pioneer city in many things. It possessed fine townways, parks, and suburbs, the Botanical Gardens were a very fine institution, the Ruskin Museum was unique, the Edgar Allen Institute compared very favourably with such a place as the Zander Institute at Arcles-Bains, and the city might certainly be proud of its doctors. Mr Kenyon Parker (the city coroner) proposed the toast of "The Medical Profession" in an appreciatively humorous speech. Mr Souttar, after acknowledging the honour done him in inviting him to reply to this toast, dealt with the subject of hospitals. He said that without the doctor and the nurse hospitals would be merely bricks and mortar. The important thing was to preserve the spirit which pervaded the work of the medical and nursing staffs under the present voluntary system. One of the first questions asked recently by an American visitor to the London Hospital was, "What do you pay your chairman?" The question of paying the staff was of trivial importance as compared with the spirit in which the work was done. The value of the hospital was recognized—patients knew, the public knew, when they had their hand on a good thing. No nursing home could touch one of the great hospitals. Why should the hospitals be limited out of sentimentality merely to the poor? In the near future the hospitals would have to be thrown open to every class. The Labour party was now putting forward hospital treatment as one of the planks in its platform, proposing to increase the number of hospital beds from 50,000 to 100,000. They would make grants to hospitals of such dimensions that even Lord Knutsford would not be able to refuse them, and they would naturally insist on having a larger hand in their control. "We do not want our hospitals to become State institutions and sterile. If the hospitals are to be maintained by the State it is up to us to see that they remain alive. It is the doctors and nurses that are the life and soul of the hospitals. We want to develop a hospital system that will be the pride of our country, as it has been in the past. Other countries have got ahead of us in some ways, they have nothing comparable with our nursing staff, nor perhaps with our personnel, but we may learn something from them in equipment. It is the union of our profession which is going to be the salvation of the hospital system." Professor A. M. Conwell proposed the health of the visitors, and Judge Turner responded in a witty speech. Dr James Mickinon, D.S.O., in proposing the health of the chairman, referred to Dr Turner's distinguished services at the front during the whole period of the war, and to his able service in former years as secretary of the Sheffield Division of the British Medical Association. The toast was drunk with musical honours.

1030 NOV 28, 1925]

SCOTLAND

SLAUGHTER-HOUSE REFORM
The fourth annual Benjamin Wild Richardson Memorial Lecture was delivered before the Model Abattoir Society in the Bunnies Hall of the Royal Society of Medicine on November 20th by Dr. W. J. Howarth, who took as his subject the health of the City of London, who took as his subject the slaughtering of animals for human consumption. The lecturer referred to the distressing conditions which prevailed in the City of London in 1850, about the time Richardson became qualified, in 58 of the 138 known slaughter houses within the square mile of the City. The slaughter was actually carried out in cellars—places which could not be adequately lighted, ventilated, or cleaned. This state of affairs doubtless led him to found the Model Abattoir Society, which, *inter alia*, desires systematic inspection of all meat carried out by competent inspectors of a local authority. Richardson experimented with the method for the painless slaughter of animals. Dr. Howarth felt that had Richardson been alive to-day he would have devised the marking of all meat that had been subjected to official inspection, so as to enable purchasers to distinguish between inspected and uninspected meat. The lecturer thought that the arrangements required in connection with the practice of marking meat would inevitably lead to the direction of private slaughterhouses by public abattoirs. The distance between slaughterhouses made it impossible for the carcasses to be inspected by a staff of thing like reasonable in number. Even if then number were reduced, would the altered arrangements prove satisfactory if they were still under private control? He feared not the only remedy was the establishment of an established factory. Without adequate compensation the slaughterer would be unwilling to surrender what some measures were liable to private right conferring on it some measure of a public charge if they had to be transported from the abattoir. The traders' objection that the carcasses were liable to damage if they had to be transported from the abattoir to the shop had not been and could not be proved. Dr. Howarth pointed out the superiority of Scottish in regulating meat inspection local authorities there were required to carry out such inspection by adequately trained inspectors. The Scottish law was strong enough to prevent the flooding of a town by meat killed in the surrounding rural areas without adequate inspection. About 1 per cent of home-killed meat in Scotland was now derived from public abattoirs. The statistics regarding meat given from the several importing countries were fully satisfactory. Austria had an excellent record, in Holland greater care was required. Obviously, in spite of inspection by foreign States, diseased meat, although probably less in quantity, was still coming through. The marking, however, enabled the inspector to be traced, and must result in better vigilance. Experience at Smithfield with home-killed meat, and especially pork, showed the need for better inspection and point of fact imported meat was less likely to be found diseased than home-killed. The lecturer then described and discussed the various methods adopted for the slaughter of animals, prefacing his account by the statement that efficient bleeding was an essential, since on it depended the quality of the meat. Although bleeding more completely by ligatures or by the use of the carotid arteries was possible than by the carotid-spiral arteries it was possible that the carotid arteries were not so far from the heart as the carotid-spiral arteries, and by mechanical means the difference was slight, and of no importance. In a country in the temperate zone observations on carcasses killed by the poleaxe and by mechanical instruments showed no difference in this respect. As for the cruelty of the bleeding method used alone, although unconsciousness might result quickly in the case of the carotids, yet owing to the supply of blood to the brain by the carotid-spiral arteries it was possible that the head consciousness was delayed and the pain of the cut felt. The animal at any rate, should be put so that the head could be properly fixed. Even under the fastest conditions the slaughtermen had been observed to use division blades to produce unconsciousness in 100 blows, and number of ovens required 125 blows of cows 127 blows, and of pigs 155 blows. The evisceration was done with only 1,259 shots.

DINNER OF THE BRISTOL MEDICAL SCHOOL
The annual dinner of past and present students of the Bristol Medical School (to which the local practitioners are cordially invited) will be held on Thursday next, December 3rd, at the Grand Hotel, Bristol, at 7 for 7.30 p.m. The dinner will be taken by Mr. I. W. Hey Groves, M.S., F.R.C.S. The guest of the evening will be Sir Berkeley Moynihan, Bt.

WIRELESS FOR THE BRISTOL HOSPITALS
On November 6th the Lord Mayor of Bristol declared the installation of wireless apparatus in the Bristol Royal Infirmary to be completed. This is the first step in the fulfilment of a plan to equip with wireless apparatus all the leading Bristol hospitals. This scheme has been staunchly supported by the Western Daily Press, which started a "Wireless for the Hospitals Fund." The equipment at the infirmary consists of a four-tube receiving set, to which are connected 162 wall plugs, providing for the simultaneous use of 324 headphones and two loud speakers. It is hoped that by the end of December the remaining local hospitals will be similarly equipped locally. The total sum covered by the Lord Mayor's Hospital Fund for the year ending September 30th, 1925, is £8,410, this exceeds last year's total by £690. The increase is largely due to the activity of the Bristol University students on their hospital day and to the response of the public to the wireless appeal.

MEDICAL TREATMENT OF LONDON SCHOOL CHILDREN
It was reported to the London County Council on November 17th that during the current year there has been a notable increase in the number of patients desiring to take advantage of the Council's facilities for the medical and dental treatment of their children. In the six months ending June 30th over 10,000 more children were treated at the Council's centres than in the corresponding period of 1924. In that year the school medical officers found a larger number of children requiring operations for enlarged tonsils and adenoids, in-patient centres for treatment of these conditions have become so popular that many parents now refuse immediate appointments for treatment of their children as out-patients and prefer to wait until they can secure appointments for treatment at one of the in-patient centres. Again, owing to increased dental inspection and to special efforts made by care committees and head teachers, more parents are seeking the importance of obtaining dental treatment for their children, more to meet the pressure on the treatment centres extra sessions have been authorized, but in spite of this children, more especially those requiring in-patient treatment and dental treatment, may have had to wait for as long as three months for appointments. This has an unfortunate effect on parents, and increases the administrative difficulties for the financial year beginning April 1st next is 35,130 eye cases, 14,680 ear, nose, and throat cases, 1,576 ringworm cases, 70,675 cases of minor ailment, and 125,950 dental cases. This represents an increase in every category except ringworm, in which there is a slight decrease. The cost of the arrangements will be £24,827, an increase of £3,875 on the expenditure authorized for the current year.

Scotland

ROYAL INFIRMARY, EDINBURGH
At a meeting of the board of managers of Edinburgh Royal Infirmary, on November 16th, it was intimated that the number of cases waiting admission had risen to 2,150. This is considerably more than two cases a bed. It was also reported that receipts during the past fortnight had reached £7,921, including a sum of £1,684 received in small amounts under the League of Subscribers scheme. Various substantial sums had also been received in recognition of from employees of various companies in recognition of

treatment received by members—namely, £100 from the Scottish Domestic Servants' Association, £362 from the Lochelly Iron and Coal Company, £226 from the employees of William Dickson, Limited, £220 from the Scottish Co-operative Wholesale Society, Leith. It was also stated that 1,574 patients had been treated in the institution during the past two weeks, and 2,151 new cases at the various out-patient departments.

EDINBURGH DENTAL SCHOOL

The Edinburgh Dental School is now making a special appeal for funds in aid of the extension of its premises at 31, Chambers Street, Edinburgh, now rapidly approaching completion. Since some years before the war the accommodation for the school has proved inadequate, and this defect has been in part supplied by the directors of the school leasing two flats in a neighbouring building. The school is at present located in a famous old Edinburgh house which, in the early years of the nineteenth century, was occupied by Lord Glenlee, a celebrated judge of the Court of Session, and formed a centre for much of the social life of Edinburgh in the time of Sir Walter Scott and Lord Cockburn. This building will not be demolished in making the extension, which will consist mainly of a new building in front of the present school, bringing it up to the pavement. The cost of the building, furnishing, and equipment of the extended premises is estimated at £17,000, and an appeal is now being made to the public for subscriptions. A preliminary appeal issued shortly before the war raised a sum of about £1,350, but the war put an end temporarily to extensions. The Dental Board of the United Kingdom, after inspecting the hospital in 1923, came to the conclusion that the proposed extension was not only advisable but necessary. In pursuance of its policy of rendering dental education as efficient as possible by making to dental schools grants in aid of approved extensions and equipment, the Board has intimated its intention of making a grant of £5,000 towards the cost of the new building and a further £1,000 towards the cost of equipment. For the balance of the sum required the directors must look to the generosity of the Edinburgh public and of old pupils of the Edinburgh Dental School. The city of Edinburgh has contributed £1,000 in five annual grants of £200, bringing the total subscription list up to £8,435 4s 6d. The extension, when completed, will be a handsome building of four stories and basement, and will include workshops, demonstration and tutorial rooms, lecture theatres, reading rooms, museum, laboratory, x-ray room, and various rooms for the patients, fully equipped for the various branches of dental treatment. The number of students attending the Edinburgh Dental School is still maintained, although there was a slight falling off after the increased entries of the post-war years. The students, like those attending the medical classes in Edinburgh, come from all parts of the world, and their presence in Edinburgh is of material advantage to the city. Over 800 students of the school have taken the L.D.S. diploma of the Royal College of Surgeons of Edinburgh since its institution.

Correspondence.

TETANUS FOLLOWING OPERATION FOR HÆMORRHOIDS

SIR,—The following tragic fatality after the comparatively simple operation for hæmorrhoids induces me to report it as it is not only unique in my own experience but in the experience of the several surgeons to whom I have related it.

On Sunday, November 1st, I operated on a miner, aged 57, for hæmorrhoids. He was prepared in the usual way, and, before starting, the rectum swabbed out with lysol. There were some half a dozen hæmorrhoids, the mucous membrane of each was snipped round the base, ligatured with strong silk, and allowed to slough off, which they did on the seventh day. A morphine suppository 1½ gr was inserted after the operation. He progressed satisfactorily, and on the sixth day had a dose of castor oil, followed by an enema. On the seventh day he talked of getting up as he

felt so well. On the eighth day he complained of stiffness of his throat. The next day he had well-marked tetanus. Within two hours 3,000 units of antitetanic serum were injected into his vastus externus muscles. He died early the next morning.

The chief points of interest in this case appear to me to be the following: (1) The thousands of similar cases that are done every day without any such infection. (2) That no catgut was used. (3) The tetanus bacillus is known to be a common inhabitant of the intestines of horses and cattle and other animals. (4) It has been demonstrated in the intestines of some men, and Tulloch has shown it to have been present in the stump of an appendix.

As such an occurrence is nothing short of a calamity it would be interesting to know if other surgeons have had the same experience, and whether it is preventable.—I am, etc.,

Rivton on Tyne Nov 16th

ANDREW SMITH, M.D.

SIR,—My friend Mr R. J. Willan of Newcastle-on-Tyne tells me that, at his suggestion, Dr Andrew Smith is sending you the notes of a case of tetanus following operation for hæmorrhoids.

Some years ago you were good enough to publish, and to make editorial comments upon, a paper by me on the subject of post-operative tetanus and its relation to catgut (BRITISH MEDICAL JOURNAL, August 17th, 1909, p. 948), and I understand from Mr Willan that some reference to that paper might now be appropriate. In it I put forward the following propositions and endeavoured to support them by rather scanty evidence:

1 That what we call post-operative tetanus is not true tetanus, but a closely allied condition.

2 That post-operative tetanus only follows operations performed in those parts of Great Britain in which diseases closely allied to tetanus are endemic—such as "looping-ill" in sheep.

3 That the offending microbe is not introduced during the operation, but is already an inhabitant, having gained admission in drinking water from infected pastures.

4 That post-operative tetanus only follows operations which involve the peritoneal cavity.

5 That whether or not the disease be true tetanus or looping-ill, and whether or not it be introduced during the operation, the infection is not conveyed by the catgut.

All the catgut which is used in the British Isles is obtained from a common source in Europe, and it would be strange if it were innocuous for the most part and only produced tetanus in those areas which are known to be infected with looping-ill.

The infectivity of the catgut (if it be the guilty agent) bears no relation to the amount used. Post-operative tetanus does not follow operations upon the limbs, in many of which large numbers of ligatures are left. It has occurred after abdominal operations in which a single ligature has been used, and it has followed similar operations in which catgut has not been used.

The evidence which I was able to gather appeared to exonerate catgut, and the contention that what we name post-operative tetanus is due to pre-existing infection by one of the allied sheep diseases seems to be worth support, based as it was upon the work of the late Professor D. J. Hamilton.—I am, etc.,

W. G. RICHARDSON, M.B., F.R.C.S.,
Honorary Consulting Surgeon, Royal Victoria
Infirmary, Newcastle on Tyne

Portsmouth, Ke Wick Nov 16th

THE METHODS OF INVESTIGATION OF NEO-CARDIOLOGY

SIR,—I desire to bring to notice a matter which to my thinking is of great importance. There is cleavage in the ranks of the profession concerning the investigation of the heart. It results in the main from the use of two instruments, the polygraph and the electro-cardiograph, both of comparatively recent introduction, the neo-cardiologists, on the one hand, claim that these are essential to diagnosis, the palæo cardiologists (I suppose we may thus style them), on the other hand, distrust the findings of these instruments as insufficiently established. There is

...st come
...ective claims
...ould plead for this

...as to the polygraph, that
...of certain venous pulsations
...modified (in disease), with respect to
...cardiac events, it deals with a purely
...problem and so belongs to physiology. This
...I have examined to the best of my ability and have
...come to the conclusion that the current interpretation
...of the polygraphic venous pulsations does not agree with
...the sequence of events in the cardiac cycle. But before
...publishing my conclusions I submitted them to Professor
...Stirling for criticism. He approved my argument and
...encouraged me to publish (*BRITISH MEDICAL JOURNAL*,
...April 14th, 1923, and November 8th, 1924), he also gave
...me permission to use his name, the authority of which
...puts my contentions on a different plane.

With regard to the electro-cardiograph and its claims
let another speak. In January, 1924, Sir James
Mackenzie published his views on a "New outlook in
cardiology" (*BRITISH MEDICAL JOURNAL*, January 5th,
12th, 19th). The articles are largely theoretic and philo-
sophic, but under the sectional heading "The use of instru-
ments" he says, speaking of the electro-cardiograph:

"At the outset I foresaw the limitations of the method in that
it would be of little use beyond revealing the nature of certain
disturbances of rhythm. As I have said the object which from
the outset of my investigations chiefly interested me was the
functional capacity of the heart or heart failure, and it was clear
to me that the electro-cardiograph would be of little or no help
in this matter" (p. 105).

This is indeed a serious indictment, if it be true, for
without question the one concern of the cardiologist is
heart failure.

Let me conclude with another quotation from Sir James,
it is prefatory and occurs on the first page of the article.
It reads:

It is not contended that the problems with which these
articles deal are solved, or that our interpretations are correct.
The interpretations are those which the present state of our
knowledge permits, and are intended to show the line along which
we are seeking the solution of medical problems.

The first sentence in the above is a strange profession of
doubt, on which to found a large superstructure of theory.
As to the second sentence, since the articles make special
mention of "the use of instruments," the pronouncement
that the present state of our knowledge permits the current
interpretations is and will continue to be challenged
so long as the reasoned objections which have been put
forward have not been met, or may the silence, which
my endeavours have thus far achieved, be taken as imply-
ing acceptance of those conclusions?—I am, etc.,

London W 1 Nov 12th

HARRINGTON SAINSBURY

FOCAL INFECTION

SIR,—Only after accumulating evidence to the contrary
did I abandon the view I long held myself which is so well
expressed by Dr A. Campbell Stark (*BRITISH MEDICAL
JOURNAL*, November 21st, p. 979) when he states:

What makes the general practitioner sceptical is that he sees
a very large number of people with an obvious septic focus who
enjoy good health to old age, and conversely no septic focus can
be found when it ought to be present.

Is it not that the active local suppuration localizes the
infection, whereas the infected focus unassociated with
polymorphonuclear cells—that is to say, pus—is most
liable to toxæmia? When the toxæmic symptoms are
more evident than the latent and apparently inactive
infective focus, this causal focus is ignored by the patient
and the practitioner's attention is concentrated on the
manifest toxæmic symptoms. At any rate, that was the
mistake I fell into till, now many years ago, I was driven
to seek and often find the causal focus—though too often
also I failed. The post-mortem wound that quickly suppu-
rates is analogous to the patient with profuse purulent
nasal discharge, while the same wound that is followed by
no local abscess but by a spreading of the infection up the

lymphatics of the arm frequently results in general blood
poisoning and death. The latter case with no marked local
disturbance is the analogue of the toxæmic case from a
latent or hidden focal infection.

Hitherto the causal factor of focal infection in many
diseases has been underestimated, but there seems a danger
of attributing to such causes more than is warranted by
well ascertained facts. If, as I believe, Dr Stark's
remarks are founded on an abstract of my recent Simon
Lecture, I venture to hope that he will do me the honour
of reading the lecture when published in full (in the
December number of the *Journal of Laryngology and
Otolaryngology*). Then any criticism or suggestions offered by
himself or any practitioner would be most warmly appre-
ciated and helpful in arriving at sound conclusions—
I am, etc.,

Bristol Nov. 23rd.

P. WATSON-WILLIAMS

THE GENERAL MEDICAL COUNCIL

SIR,—There is a tolerably widely spread feeling in the
medical profession that the General Medical Council
requires a good deal of overhauling. It has, in great part,
lost the confidence alike of the public and of the medical
profession. Into the general question I do not propose
to enter just now. I wish only to discuss one point, and
that is its penal functions.

I have a feeling that its present powers of pit and
gallows should be considerably reduced. As a matter of
fact, so far as I am aware, there is no member of the
General Medical Council who is a trained lawyer, is
individual members, so far as law is concerned, are
amateurs. We are told, and no doubt quite true, that
they always have their solicitor with them for purposes of
consultation, but that simply amounts to this, that the same
man who draws up the libel or indictment is the same man
who advises them as to its relevance, and is the same man
who advises them as to whether the libel or indictment has
been proved or not. There can be little objection to the
General Medical Council acting as a court of first instance,
but unquestionably on all points which have any legal
bearing before a man is deprived of the means of earning
his living he should have the right of appeal to an ordinary
legal tribunal, in England he ought probably to have an
appeal to the Criminal Appeal Court and in Scotland to
the High Court of Justiciary. I have no wish whatever to
shelter black guards, and certainly if a man has been con-
victed in any criminal court of a serious offence he ought
not to have the right of appeal. But apart from that,
there should invariably be a right of appeal, at any rate
on points of law and on the value of evidence.

One other point I think should be attended to, and it
is that cases occurring with practitioners in Scotland
should invariably be heard in Edinburgh or in Glasgow by
the Branch Council of the General Medical Council, and
ought not to go to London. A Scottish practitioner who
may be in trouble must, if his case is to be properly con-
sidered, fee lawyers both in Scotland and in London, or
else be at the enormous expense of taking his lawyer
up with him. Further, it entails considerable travelling
expenses, and probably hotel expenses for himself. The
Branch Council for Scotland is quite a large enough body
to sit as a court of first instance.

There are many other changes that ought to be made
in the General Medical Council, but one thing at a time
is quite enough—I am, etc.,

FREELAND FERGUS

Glasgow Nov. 20th

A MEDICAL MINISTER OF HEALTH

SIR,—My friend Sir Lenthal Cheate seems to hold the
original view that all the ills from which the medical pro-
fession is now suffering would vanish if the Ministry of
Health were presided over by a medical man, he is
optimistic enough to imagine that, given that "reform,"
medical teaching would improve, unqualified practice would
cease in the land, and operating surgeons would be spared
the present inconvenient competition from the pupils whom
they teach. He developed this thesis more fully in the
address (mentioned in your columns November 21st, p. 981)

which he gave to the Parliamentary Medical Committee last week, but some of it appears in Sir Lenthal Cheate's address (p 958), which provokes this letter. I would ask your permission to deal with a few of these contentions.

1 I am convinced that the first cardinal principle which we should grasp is that it would be foolish to dissipate our strength as a profession in running counter to a thoroughly entrenched public opinion. There is a significant and pertinent passage in Lord Grey's recent memoirs which to my mind states with final authority the case against a medical Minister of Health.

"The theory and practice of parliamentary government is not that of government by experts but by men of general experience and proved capacity, presiding over experts who are the civil servants in our public affairs."

The success which has attended this "theory and practice of government" is such as to give no warrant, and to produce no desire, to alter it.

Administration must inevitably form by far the greater part of the work of a Minister of Health. Sir Lenthal Cheate mentions a grievance which the directors of medical units are pressing at the present moment—namely, that their time is so largely taken up by administration. How much more must this be so in the case of the Minister of Health. A medical Minister of Health would not command the respect of the profession outside of the House of Commons unless he were also a leader in medicine. Sir Lenthal points out that no man can be a leader in medicine unless he is doing original work in his profession. It is clearly impossible that the Minister of Health should be a leader in medicine and at the same time perform the duties of the head of a great Government department. Sir Lenthal's suggestion is not practical from any point of view, and that was the predominating opinion expressed at the meeting of the Parliamentary Medical Committee last week.

2 I submit that the teaching of medicine must lie in the hands of those who are actively practising it, and it would be disastrous to have theoretical systems of teaching imposed from outside upon our schools by doctrinaires, wholly divorced from practical experience of medical education. It is, in fact, a danger inherent in the present position of the unit system in London, that it is financially dependent upon a Treasury grant, and therefore potentially at the mercy of such doctrinaires. To have the system of teaching also dictated by a Government department would immeasurably increase the peril to our medical schools.

3 I submit that it is the task of the medical profession itself to combat the spread of unqualified practice, not by legislative measures, but by wise competition with this unqualified practice. To adopt an ostrich-like policy of deluding oneself that the evil does not exist, or to wait for some *deus ex machina* from the Ministry of Health to remove it, is merely fatuous. In using the term "wise competition" I would especially emphasize the need to inquire into, and, if found valuable, to adopt and to improve upon, methods of treatment, irrespective of their origin, whether orthodox or unorthodox. If the inquiry proves that a cult, with a large vogue, nevertheless rests upon demonstrably unscientific foundations, exposure of those unscientific foundations should be undertaken by leaders of the profession competent to expose them.

4 Sir Lenthal Cheate thinks that teachers of surgery should be highly salaried officers apparently because the competition from what he calls "decentralized areas" is depriving the consulting surgeon of the handsome remuneration to which he has long looked. I submit that this competition has been successful because the operating surgeon exacted fees out of all proportion to his economic value, a reaction was bound to come, and indeed has come. Here is a concrete illustration given to me by a friend of mine in general practice in the suburbs of London of the exaggerated value put upon the services of the operating surgeon. My friend in the same week called down to his assistance a surgeon and later a physician to assist him in two different cases. Both were members of the staff of his old hospital. The surgeon performed an operation which took him exactly half an hour, and never saw the case before or after that single intervention. The

physician spent well over an hour in a very examination of the patient, and entirely revolutionized the diagnosis and treatment. The surgeon's fee was one hundred guineas, the physician's fee was ten guineas. It is this glaring disparity which more than any other circumstance has rendered possible the competition that Sir Lenthal Cheate describes.

There can be little doubt that the hospital surgeon of the future will have to be satisfied with something like the same remuneration which rewards his colleague the physician. Even if hospital teachers should become highly paid whole-time men, the salary available cannot approach the income to which operating surgeons have become accustomed. It has been the common experience at the medical schools with units that while the professorial remuneration (£2,000) allotted to the heads of units has attracted a large field on the medical side, it has been extremely difficult to fill the surgical posts. Appointments to the unit are at present made by the Senate of the University of London, and considerable dissatisfaction is already expressed in many quarters of the University at the disproportionate salaries allowed to the medical professoriate as compared with professoriates in other faculties. It is not altogether surprising that such dissatisfaction should be exhibited when one reflects that on the same agenda paper of the Senate one may find a recommendation that the salary of, for example, a professor of mathematics of European reputation should be increased to £900 after perhaps fifteen years' service in the University, and that the salary of a young medical man commencing his professorial career should begin at £2,000. It is at any rate quite certain that no public body will ever consent to establish the salary of the surgeon at a figure something like ten times as large as the salary of his colleague the physician, which is the ratio which the present scale of fees seems to warrant.—I am, etc.,

London W1 Nov 21st

E GRAHAM LITTLE

POISONOUS DOMESTIC CLEANING FLUIDS

SIR,—I am deeply interested in the problem of poisons, their uses and abuses. In my own courts I have seen only too often the fatal results that follow when such poisons as spirits of salts, salts of lemon, etc., are taken either deliberately or accidentally. I have often suggested that more stringent regulations affecting their sale should be enacted and have frequently commented on the potency of these domestic poisons and the terrible effect that they have on the human frame. Surely this evil can and should be avoided. There is, for instance, a perfectly well known and entirely non-poisonous substitute for spirits of salts, and there seems no excuse for the continued laxity in the sale of this poison.

I am open to correction, but in some foreign countries, I understand it is only from the regularly licensed druggist that poisons such as spirits of salts can be obtained by the public. It seems to me that we in our country might do something to follow this example.

These poisons are widely used, but it must not be forgotten that they are also widely abused. To restrict the sale of them would be more of an advantage than a disadvantage to the public at large, and would help to remove a real peril from our midst.—I am, etc.,

round. The crying
number of masseurs
of this all-important branch
short of criminal. If we could
as it is done in Sweden or Japan the need
would disappear. A well trained masseur
under medical supervision would fill the gap
I am, etc.,

Long Sutton Walsby, Nov 15th.

R MURRAY BARROW

SIR,—Dr Manson courteously corrects the verbal misquotation in my description of the Warrington motion. As he writes (November 21st, p 980), the proposal was that "no unregistered person be allowed to practise medicine or surgery," not that "no unqualified person" should be so hindered. I agree that the reference ought to have been accurate in every particular, and I the more regret the error, as it now appears that Dr Manson regards a distinction between the meanings of the two terms to be important in the development of his argument. In his original letter (November 7th, p 868) he describes the motion as one "on unqualified practice," and later writes about "unqualified osteopaths" and about "checking or discouraging unqualified practice." Personally, I understood the term "unqualified," as used in these phrases, to mean, in accordance with the custom of medical discussions, a person not trained, examined, and certified according to the regulations of the General Medical Council. In this sense the difference between "unqualified" and "unregistered" is in practical affairs a minimum quantity.

But I now learn that Dr Manson's "registration" is something much larger than the present practice. He anticipates, were Parliament converted to his view, that "all manner of healers would clamour for admission to the Register, and by this means receive legal status and official recognition." In the sense of this proposition the difference between "qualification" and "registration" is, indeed, a wide one. Yet the development has a startling quality when advanced by an advocate who at Bath claimed that "the whole range of medicine should be kept for those properly trained for the job," and I confess that until his latest letter I had never suspected that Dr Manson's project of "registration" was marked by so comprehensive a charity. Whether in this respect I have been inexorably slow of understanding I cannot say, but in any event my contention that the vote at Bath cannot be held to imply "apathy" to the "unqualified osteopaths'" desire for registration remains unchallenged.

A small point, and a final one, and a question of accuracy. To "talk out" a motion means, I suggest, to speak on the motion at such length that an opportunity for a vote is denied. But this is not what happened at Bath. What brought the Warrington proposal to naught was not an individual speech but the deliberate decision of the meeting.—I am, etc.,

London, W 1 Nov 23rd.

C O HAWTHORNE

THE LEAD TREATMENT OF CANCER

SIR,—You did me the honour to invite my views regarding Professor Blair Bell's cancer research, and this, I think, justifies comment on my part upon the leading article which appeared in the same number as my letter. What impresses me, I confess unfavourably, regarding that leading article is that the writer very significantly neglected to comment upon Blair Bell's supreme achievement—namely, his discovery of a means whereby the death and absorption of the cells of malignant growths can be brought about by an agent of known composition administered in known doses. Herein, and not in the successive steps of his hypothesis, is the all-important advance. That hypothesis is of value, first, as affording evidence that this is no mere empirical discovery, even though it is based upon the long-established empirical employment of lead to

induce abortion. But, starting from this point, it is the outcome of a train of careful reasoning and experiment. Secondly, it is of value as demonstrating the use of the more recent developments in physical chemistry for the opening up of attack upon pathological problems. If a hypothesis, when acted upon and put to the test, yields the expected result it at least deserves consideration. If it does not contain the whole truth it must contain a very essential portion of that truth. That this hypothesis has led to results those of us can have no doubt who have seen superficial tumours in man and in the lower animals after intravenous injection of colloidal lead slough out in their entirety.—I am, etc.,

University of Liverpool, Nov 24th

J GEORGE ADAMI

CLOCKWORK CONTROL OF THE CARREL-DAKIN TREATMENT

SIR,—I have read with interest Professor Cathcart's article on the above subject in your issue of November 21st (p 933). It would appear from this article that Professor Cathcart is not aware that Dr Carrel adopted the clockwork magnetic control method in his hospital at Compiègne, near Paris, during the war. I had the pleasure of seeing the method working most efficiently when I visited the hospital in 1917.—I am, etc.,

London, W, Nov 23rd

C GORDON-WATSON

AN UNUSUAL ANAESTHETIC FATALITY

SIR,—In a recent case of the explosion of a mixture of ether vapour and oxygen during a dental operation in which a warmed syringe was used (reported in your issue of October 17th, p 713), the suggestion was made at the inquest that ignition had been caused by a flame some six feet away.

I would suggest that ignition may not have been caused by the flame but by the syringe. If a platinum needle were in use, the conditions would have been especially favourable for producing a catalytic action on the surface of the warm platinum, thus leading to the ignition of the mixture of ether and oxygen. Even in the absence of platinum it is not improbable that some metallic part of the syringe acted in a similar manner, nickel, iron, and even glass and porcelain being known to possess catalytic activities in a greater or a less degree.—I am, etc.,

BERNARD D BOLAS, M Sc Lond

London W 4 Nov 19th

ANAESTHETICS IN CHILDHOOD

SIR,—I do not agree with Dr Singleton when, in his paper on anaesthetics in childhood (November 14th, p 900), he states that "induction by chloroform and mixtures containing it is dangerous." It is by no means so if it is properly administered. I am rather partial to the giving of anaesthetics, and have administered chloroform and chloroform alone 2,310 times since 1900 without a fatal issue. In my experience children take it exceedingly well, be it for dental or any other operation.

The adult male alone has given me any concern, no doubt due to the influence of alcohol or nicotine, or both, upon the myocardium, but very rarely indeed was there any cause for anxiety. Two patients only (females at the close of pregnancy) died later from acidosis—surely very few out of such a total.

I consider chloroform to be the best of all anaesthetics, provided an overdose is not given. I do not believe in the so-called status lymphaticus. Such fatal cases must be due to "the little more, and how much it is." If chloroform, or any other general anaesthetic, is administered carelessly and in sufficient bulk, there will undoubtedly be engraven on the memory the recollection of a few tombstones in the neighbouring cemetery.—I am, etc.,

Cowdenbeath Tife Nov 19th

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT]

PARLIAMENT began its business this week with tributes from both Houses to the late Queen Alexandra, and decided that there should be no sitting on Friday. Thursday was devoted by the Commons to a debate on unemployment, and the preceding days to the report stage of the Rating and Valuation Bill. The Government is pressing this bill into law as a preliminary to reform of the Poor Law.

The Minister of Health is understood to have a Poor Law Reform Bill ready for introduction next session, provided the Cabinet agrees to find time for it. A draft of its proposals has recently been circulated to local authorities. Mr Neville Chamberlain proposes to abolish boards of guardians, to constitute, so far as possible, one local authority financially responsible for each area, and to avoid duplication of health services. Mr Chamberlain also proposes as an integral part of this scheme to abolish percentage grants from the Treasury to local authorities, and to fix a block grant to each authority for a term of years, this grant to be expended as the authority thinks fit, subject to the maintenance of a general standard of efficiency in local services. As the rating and valuation reforms now before Parliament do not become fully operative till 1928, the block grant system cannot be introduced till later.

The Government regards this Poor Law scheme as the complement of the National Health Insurance schemes already adopted. When the bill is submitted it will be pointed out that in every area of the country the guardians deal with destitution, while other local authorities deal with housing, water, sewerage, and roads. Hospital provision for the destitute through the boards of guardians is growing up side by side with the provision by other local authorities for other services, such as nursing or expectant mothers and the tuberculous. There is, moreover, the voluntary hospital system. When the Poor Law Bill comes before the House the Government is likely to argue that if health and hospital provision in any area is to be effective and economical it must be handled as a whole by a single health authority. The Government will also point to the danger of overlapping in public services from the fact that a person in need through old age, unemployment, sickness, or disability can at present obtain this assistance either under the National Health Insurance schemes, or in some instances from the local authorities by maternity or tuberculosis schemes, or from the guardians or from voluntary organizations. The Government is likely to propose that in each local government area a single authority shall concert these efforts and ensure that double assistance is not given. The achievement of this co-ordination, embracing apparently the voluntary hospitals, is declared to be an essential part of the Government's Poor Law reform scheme. In county boroughs the unitary health authority will be the borough or city council. Whether in counties the work will be divided between the county council and district councils is not authoritatively revealed.

Confident assertions are heard to the effect that the Royal Commission on National Health Insurance, which may report early in the new year, has decided to recommend that in the next valuation period £1,000,000 be allocated from health insurance funds for specialist services, and £2,000,000 for other optional benefits. A strong minority of the Commission is reported to favour the abolition of the approved society system and the reorganization of National Health Insurance on a regional basis.

The Medical Committee of the House of Commons held its inaugural meeting for the autumn session of Parliament on November 23rd.

Health Insurance

Sir Kingsley Wood stated that the Minister of Health was aware that a charge was sometimes made by panel doctors for a medical certificate for a patient's private employer though he had no information on the extent to which the practice prevailed. The National Health Insurance Act did not provide for the issue of such additional certificates free of charge, and to secure this would require legislation.

Answering Mr Forrest, the Minister of Health said he could make no statement of the intentions of the Government regarding the proposal to reduce the contributions under the National Health Insurance Act.

In reply to Mr Forrest, Mr Neville Chamberlain said the additional benefits now being provided by approved societies out of surpluses disclosed on a valuation included (in addition to increases of the standard rates of sickness, disablement and maternity benefits) dental benefit, ophthalmic benefit, treatment in convalescent homes, the provision of medical and surgical appliances and payments to hospitals and for nursing. Dental benefit had already been adopted in England by 794 societies and 2,662 branches, and these numbers would no doubt be increased when the whole of the schemes following the second valuation had been formulated.

Dr Shiels asked the Minister of Pensions whether the superintendent and medical officer of Edenhill Hospital, which had been replaced by English doctors and if there were any professional or other qualification possessed by the new superintendent which the late one had not. The Minister of Pensions (Major Tryon) replied that these staff changes had been necessitated by the recent conversion of this hospital from a general neurotic hospital into a neurological institution of a special and different type. The claims and qualifications of the late medical superintendent were fully considered before it was decided to replace him by a medical officer possessing more specialized neurological experience, and this decision involved no reflection upon his general professional ability or upon the efficiency of his past service with the Ministry. The question of the nationality of the officers concerned did not enter into the comparison.

Major Tryon, answering Mr G Harvey, said that in consequence of refusal by firms of limb makers hitherto under contract with the Ministry for the supply of metal artificial legs, to renew their contract except on terms which would have imposed an increased charge on public funds, he had, on the report of a committee of inquiry, reduced the number of firms with which contracts had been made for the supply and repair of metal artificial legs to two. He had received a deputation representing ten firms which had ceased to hold contracts, and had informed them that the decision could not be reconsidered. The limbs supplied by the two firms selected were of the first quality.

Lieut Colonel Stanley stated that the number of appeals by men against the termination of their pensions rejected by the appeal tribunal on the ground of being out of date was 5,000. No claims to pension for tuberculosis or any other disease have been rejected on the sole ground that the applicant was found to have suffered from the disease prior to enlistment. On the completion of the reclassification of the Midlands Region on December 5th there would remain only two regions—Northern, with headquarters at Newcastle on Tyne, and Scotland, with headquarters at Edinburgh.

Detention of Lunatics

Commander Kenworthy asked the Minister of Health whether prior to the escape of Prince Ahmed Seif ed Din from Titchmarsh Asylum, repeated efforts to have him examined by independent specialists had been refused. Mr Neville Chamberlain said Prince Ahmed was confined in an asylum in this country from July, 1900 to September, 1925. During that period he had been frequently seen by medical and legal Commissioners of the Board of Control. Within a year of his original detention a special visit was paid to him by a medical commissioner, and a similar special visit was paid as recently as July, 1924, when the commissioner was satisfied that the Prince was insane and properly detained. In September 1924, the patient was examined by three independent specialists, two being eminent alienists of this country, and one a specialist from Zurich. They also expressed the view that the Prince was definitely of unsound mind. A further application for an examination by independent specialists was made to the Board in the same month but was declined because it was considered that another medical inquisition at such short interval might be detrimental to the patient's health. Mr Chamberlain added that he had no information supporting the statement that the Prince had established his sanity since leaving this country but, judged by the standard of conduct recognized in this country, he was undoubtedly insane at the time of his escape.

Answering Mr Hayes, the Home Secretary said that J. G. Prickett, now in inmate of Broadmoor Criminal Lunatic Asylum, had not been certified sane. Applications for his discharge had been considered carefully. The Home Secretary added that he did not feel justified in ordering Prickett's release.

Salaries of Medical Officers of Health.—Sir Frederick Hall asked the Minister of Health whether seeing that the Bethnal Green Metropolitan Borough Council recently approved a proposal for the appointment of a medical officer of health at a salary of £800 rising to £900 a year and that the Ministry of Health intervened and expressed the view that the commencing salary should be not less than £1,000 and in view of the recognized need for public economy and the fact that the salary offered by the borough council was considerably more than the income earned by a number of able highly trained general practitioners he would state the general principles which had actuated the Ministry in taking this line. Mr Chamberlain replied that the salary first proposed by the borough council was considerably below the standard arrived at as appropriate to such an area after lengthy discussions between representatives of the Ministry of Health and of the British Medical Association and Society of Medical Officers of Health with the assistance of advice from gentlemen of standing in the field of local government. He felt it impossible to approve the proposal of the authority and had sanctioned a temporary appointment. Dr Shiels asked the Secretary for Scotland whether he was aware that the Scottish Board of Health recently advertised for a medical officer (woman) at a salary of £500 rising to £800 whether this was the same scale of salary as was applicable to medical officers (men), whether the salary was substantially less than that paid to medical officers of similar qualifications and discharging similar duties employed by the Ministry of Health and if so, what were the grounds on which the difference was based. Sir John Gilmour said that the salary quoted excluded the cost of living bonus. Including this bonus, the minimum accordingly was £684 and the maximum was £1,009. The same scale was applicable to men. He understood that a higher scale was payable to medical officers in the Ministry of Health. The salary scales referred to were the result of long negotiations turning on general considerations outside the scope of parliamentary questions and answers.

and Iul Winterton (Parliamentary Secretary) informed Mr Grenfell that the recommendations of the Lee Report as to the constitution of medical services in India had been accepted, subject to the need for maintaining for army requirements a reserve of medical officers in civil employ, and for providing medical attendance by British doctors for British members of the services. It had been decided to maintain the Indian Medical Services in substantially its present form to meet army requirements, and the Government of India was now considering how best to adapt the civil branch of the service to the general scheme of medical reorganization.

Royal Commission on Lunacy—On November 18th Sir Charles Oman asked the Minister of Health whether any further evidence from former inmates of asylums was to be taken by the Royal Commission on Lunacy, and whether requests for permission to give such further evidence had been received by that Commission during the last few months and refused. Mr Neville Chamberlain said he understood that the Royal Commission, having heard oral evidence from thirteen former inmates of asylums, and considered a large number of written statements, did not propose to take further evidence of this nature. During the last six months eight applications had been received from former inmates desiring to give oral evidence, but the Commission had been unable to comply with these requests.

Cancer Clinics—In answer to Mr Forrest, Mr Neville Chamberlain said he was aware that free clinics had been established in the United States whereat all persons with suspicious growths were able to attend. In this country, at numerous out-patient departments of general hospitals and other medical institutions (specialized for the treatment of cancer or otherwise), persons who suspected that they had cancer could receive the early stages of cancer could receive advice and treatment. In July 1923, the Department on Cancer made certain recommendations on the way in which local facilities for early diagnosis and treatment of this disease might be improved by local action. These recommendations were embodied in a circular issued to local authorities in August 1923, and were now being followed in several of the larger cities.

The Spahlinger Treatment—On November 20th Mr Vernon Davies asked the Minister of Pensions whether the information available in his department regarding the Spahlinger treatment was sufficient to justify him in arranging for the provision of this form of treatment for pensioners suffering from tuberculous. Lieut Colonel G F Stanley, replying for the Minister, said: "No Sir, the matter is one primarily for the Ministry of Health. The Minister of Pensions understands that the case must still for the present be considered 'not proven'."

Opium in India—Earl Winterton stated in reply to a question, that about the beginning of this year the Government of India addressed local governments, drawing attention to some evidence of abuses of opium in various directions, and asked them to examine the question and to co-ordinate with the Government of India whether this evidence made it desirable to revise the conclusions of the Royal Commission of 1893. In September last the Government of India stated that it was still awaiting the replies of local governments.

Bakers' Dermatitis—Sir W Joynson Hicks informed Mr Forrest that no legislation was contemplated to deal with the spread of dermatitis among bakers but the issue of an Order was contemplated which would require the adoption of special precautions. Dr Tremantle asked whether the administration of the Home Office should not be brought into touch with that of the Ministry of Health when dealing with such matters. The Home Secretary said he did not see how that question arose. Replying to a question on the causation of dermatitis, Mr Neville Chamberlain said the effect on the health of the consumer from the treatment of flour with improvers and other chemical substances was under investigation by a Departmental Committee, and, pending its report, he could not entertain a proposal to make restrictive regulations. So far as he was aware boric acid was never added to flour.

Kenya—On November 23rd Mr Amery (Secretary for the Dominions) informed Mr H Williams (1) that according to a return published on January 21st last, there were 76 registered medical practitioners resident in Kenya of whom 32 were European Government medical officers. (2) that 29,402 cases of yaws were treated at Government hospitals and dispensaries in Kenya during the year 1924 and in addition 16,125 cases were treated by Government medical officers while on tour in their districts either at out-dispensaries or otherwise. It was impossible to estimate the number of cases which did not come to the notice of medical officers. The need for medical research in East Africa was appreciated by the Government.

Foot and Mouth Disease—Sir Harry Burns, on replying for the Ministry of Agriculture to questions concerning foot and mouth disease, said the Government was attempting to obtain amongst other things a safe and effective method of preventive inoculation against this disease. In the work with this object was being carried out at a specially constructed cattle station at Pirbright.

Veterinary Treatment—Sir W Joynson Hicks (Home Secretary) informed Captain Gee that treatment of animals by a person not having a veterinary qualification was not an offence against the law. The Protection of Animals Act forbade, *inter alia*, any person

or unreasonable act causing unnecessary suffering and any operation "performed without due care and humanity," but he had no reason to suppose that the work of the People's Dispensary for Sick Animals, the object of which appeared to be the relief of animal suffering, was carried on otherwise than with care and humanity.

Answers in Brief

Sir S Hoare (Secretary for Air) informed Sir F Hall that the number of fatal accidents during the twelve months ended September, 1925 due to aeroplanes crashing was 42 involving 57 deaths.

The second reading of the Bethlehem Hospital Bill which has passed through the Lords, was put down for Monday, November 23rd, but objection was taken by Dr Haden Guest and other members, and the second reading was therefore postponed.

On November 23rd during the report stage of the Rating and Valuation Bill, Mr Barker moved a new clause to exempt underground sewers from rating. Mr Neville Chamberlain (Minister of Health), in replying, said he hoped next year it might be possible to introduce a bill to amend the Public Health Acts, and, if so, that might be a suitable opportunity to deal with the matter. The clause was negatived.

Mr Neville Chamberlain hopes to introduce next session a bill dealing with smoke abatement.

The population of England and Wales is estimated to have increased between the census of 1921 and the middle of 1925 by 1,003,000.

The provisions of the Public Health Act, 1925 dealing with the conditions under which meat is stored or sold in shops apply also to fish.

It is not prepared to remove the present requirement that persons to be vaccinated before enlistment in the Air Force.

The Ministry of Health has no record of any request from a medical officer of health asking that advice and instruction on birth control should be given at maternity centres to married women on the recommendation of medical men.

The Minister of Health had not received up to the end of last week a reply to the letter he addressed in May to the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease regarding the alteration of the law on the sale by chemists of preventives of venereal disease.

During the current financial year a grant of £5,500 has been given by the Government to the British Social Hygiene Council, and this is being expended on educational work approved by the Ministry of Health.

Steps will be taken to set up, early next session, the proposed Select Committee to inquire whether legislation is desirable for registering and supervising nursing homes.

The Services.

DEATHS IN THE SERVICES

Surgeon General Howard James McChesney Todd, C.B., K.H.S., R.N. (ret.) died suddenly at Gosport on November 6th, aged 70. He had sat on the Bench at Gosport police court during the morning and on his way home was suddenly taken ill entered a shop to rest, and there died. He was the son of Mr M G Todd of Hove, was educated at St Thomas's, and took the M.R.C.S. and L.S.A. in 1876. He entered the navy soon afterwards. He served in medical charge in the Niger expedition in 1879, landed with the Naval Brigade, and was present in an engagement at Onitsha. His name was mentioned in dispatches. He received the thanks of the Admiralty for his services in the epidemic of yellow fever at Jamaica in 1885-86 and was recommended for promotion; he was thanked by the Foreign Office for his services as acting consular surgeon at Mapanda's kraal in 1891. He received the C.B. at the Coronation in 1911 and was appointed honorary surgeon to the King in the following year. He was also a justice of the peace for Hampshire. In 1893 he married the daughter of Mr E Haynes of Trimbleby, Yorks, and had one son and two daughters.

Lieut Colonel John Lloyd Thomas Jones, Bombay Medical Service (ret.) died in London after a long illness, on November 12th, aged 63. He was the fourth son of the late Rev Thomas Jones of Tremadoc, Carnarvon afterwards of Criccieth and was educated at St Bartholomew's Hospital and Durham University where he graduated M.B. in 1885. He took the M.R.C.S. in the same year. In 1893 he took the D.P.H. Camb. He entered the I.M.S. as surgeon in October, 1887, became lieutenant-colonel after twenty years' service and retired in April, 1918. Most of his service was spent in the Assay Department in which he held the posts of deputy assay master of the Bombay Mint, assay master of the Calcutta Mint and assay master of the Bombay Mint, successively. Before joining the Assay Department he had the ordinary experience of an I.M.S. officer after a period of military service he was in civil charge at Ratnagiri and Karwar, and was later civil surgeon at Kaira, Broach and Aden. In 1897 he was appointed on famine duty and served as sanitary commissioner and plague officer at Poona. He did much to overcome native prejudice to segregation and received the thanks of the Government of India. His funeral took place at Tabor, near Criccieth. Among those present were his brothers, Sir Robert Armstrong Jones and Mr Towden Jones, and his nephew, Sir Thomas Carey Evans.

Universities and Colleges.

ROYAL COLLEGE OF SURGEONS

ANNUAL MEETING OF FELLOWS AND MEMBERS

THE annual meeting of Fellows and Members of the Royal College of Surgeons of England was held on November 19th. The President, Sir JOHN BLAND SUTTON, Bt., was in the chair, and the attendance was much larger than in recent years.

Dr HADEN GUEST, M.P., moved the usual resolution affirming the desirability of admitting Members to direct representation upon the Council of the College, which, as at present constituted only represented those Members who held the Fellowship. The resolution went on to urge that the constitution of the Council should be in keeping with modern ideas of true representation and more in conformity with the present day requirements of Members and Fellows, and that the opportunity afforded by the application to the Privy Council for a supplementary charter to give authority for certain changes should be taken to insert a provision therein for some representation of Members, as such, upon the Council. Dr Guest said that it was remarkable that in a body which contained so large a proportion of Members to Fellows (17,361 to 1,786) the Members should have no direct voice in administration and control. He did not wish so much to criticize the method of control in the past as to suggest that it was not adequate to the present time. The situation was also remarkable because similar resolutions had been carried year after year and nothing had been done. In the House of Commons, if a resolution was passed once, it might not become operative for various reasons, but if it was passed twice there would be some threatening even in the most adamant of Governments, and he could not conceive the House of Commons or any other public body having a resolution passed thirty six times and taking no notice of it. The College had great powers of control and direction in the matter of examinations and medical and scientific education, and it would surely be advantageous to have the experience of the ordinary general practitioner brought into its councils. Again, the College owned £400,000 worth of property, but this was managed, as also was its large income, entirely by the Fellows—no doubt with exemplary correctness from the business point of view, but perhaps not in the best way possible to carry out the duties imposed upon the College by Act of Parliament. The opportunities available to the College for guiding research were not as well used as they might be if Members were added to the Council. The College might become an active body in scientific investigation, and a vast unused store of knowledge and capacity might be made available to it, if only the general body of Members, so very many of whom were general practitioners, were brought into consultation and linked in some organic way with its work.

Mr LAWSON DODD, in seconding the motion, said that the frequent argument that the Society of Members was a small body was not relevant. The size of a society had no relation to the justice of its claims. This was a demand on the part of children for a closer union with the parent—rather a refreshing thing in these days. If there was apathy in this matter it was due to want of function. The way to remove apathy was to give the Members some connexion with the Alma Mater from which they had derived their privilege to practise. The possession of great wealth and power by a section of the community, and especially by a section of the profession did not tend towards affection and good relationship, and especially was this the case when the power had been filched from the larger body and concentrated in the smaller. With a closer link between the rank and file of the profession and the Council the number of individual benefactions to the College, which in the past had been very small, would possibly be greatly multiplied. He reminded the Council that this was not the demand of an ultrate community for the extension of a franchise; it was the demand of colleagues, men whose history had been the same as those to whom they appealed, differentiated perhaps only by a year of additional training. The concession which was being asked for was not such as to weaken the Council, on the contrary, it would enormously strengthen the Council; the result would be to give the College greater authority, wider sanction, larger influence in the eyes of the public, and the granting of this request would bless not only him who received but him who gave.

The motion was supported by Dr I. G. LLOYD, Dr ARTHUR HAYDON, and other speakers, and was carried, with three dissentients.

Sir JOHN BLAND SUTTON said, in reply, that he would not attempt to traverse any of the remarks made by the mover and seconder of the resolution. The decision on this matter did not rest with the President, as some of the speakers

seemed to think, to his disparagement. The Council, of whom the President was merely the spokesman. But he would tell the Members that the Council was anxious to get a supplemental charter, and had already received a deputation from the Members with regard to the terms of the charter. The Council intended to give the matter its very serious consideration, and for this reason, that the Council was a changing body in the way of its membership, there had been great changes in the Council by death and resignation during the last few years, and he thought, and his colleagues thought, that it would be a good opportunity to ascertain the earnest wishes of some of their younger members. They intended to give this matter very earnest consideration, and that without any delay, before the supplemental charter was sent in to the Privy Council (Loud applause).

UNIVERSITY OF LONDON

A COURSE of five lectures on the physiological and pathological activities and functions of bacteria will be delivered in the theatre of the Royal College of Surgeons, Lincoln's Inn Fields, W.C., by Dr F. W. TWORT, superintendent of the Brown Institution, on December 7th, 8th, 10th, 11th, and 14th, at 4 p.m. Admission is free, without ticket.

UNIVERSITY OF BRISTOL

THE Long Fox memorial lecture will be delivered by Dr CAREY F. COOMBS in the Physiological Theatre of the University of Bristol on Wednesday, December 9th at 8 p.m. The subject selected being, the etiology of cardiac disease. Medical practitioners are cordially invited.

SOCIETY OF APOTHECARIES OF LONDON

THE following candidates have passed in the subjects indicated:

SURGERY—T. M. Beattie, N. Cohen, S. E. Henty, M. Hook, B. Horwitz, J. M. F. Whitby, D. Winstanley.

MEDICINE—V. G. Crowley, N. O. Ghose, B. D. Jau, E. Reisel, E. W. D. Long, J. Mindess.

FORENSIC MEDICINE—M. Bannounah, A. M. El Mishad, C. L. Froehlich, M. Hook, J. Mindess, S. R. G. Pimm, L. A. Rostant, F. Wladko.

PHARMACY—C. L. Froehlich, F. W. Hayward, S. L. Henty, F. G. Martin, H. A. Sack, F. Wladko.

The diploma of the Society has been granted to Messrs C. L. Froehlich, M. Hook, F. G. Martin, and D. Winstanley.

Medico-Legal.

DIAGNOSIS OF DISLOCATION

FREEBORN & LEEMING

THE Court of Appeal, consisting of Banks, Scrutton, and Atkin, L.J.J., on November 20th dismissed the appeal of Mr. George Freeborn from the decision of the Divisional Court of the King's Bench allowing the appeal of Dr. Robert Leeming, medical officer to the Kendal Board of Guardians, from a judgement of Judge Chapman in the Grimsby County Court mulcting Dr. Leeming in £1,800 damages for negligence in failing to diagnose Mr. Freeborn's dislocated hip. Previous proceedings in the county court and the Divisional Court were reported in the BRITISH MEDICAL JOURNAL on March 14th (p. 534) and June 27th (p. 1200). It was admitted that Dr. Leeming was within the protection of the Public Authorities Protection Act, 1893, which provides by Section 1 that "the action shall not lie or be instituted unless it be commenced within six months next after the act, neglect, or default complained of, or, in case of a continuance of injury or damage, within six months next after the ceasing thereof, and the question on appeal was whether the plaintiff commenced his action within the prescribed time.

The facts shortly were that on September 5th 1923 the plaintiff was run over by a motor car, his hip being dislocated, and on September 6th he was conveyed to the Kendal Workhouse Infirmary where he was treated by the defendant. Whilst no constitutional relation existed between the plaintiff and the defendant, it was not denied that the defendant was under a duty to exercise reasonable care and skill. The plaintiff left the infirmary on October 16th 1923 by his own desire and was seen by other doctors who discovered the dislocation. Owing to the lapse of time, however, its reduction had become impossible and an operation resulted in a shortening of the leg rendering the plaintiff permanently unfit for heavy work. The county court judge found as a fact that the defendant did not make any proper or sufficient examination of the plaintiff on admission to the infirmary, and did not discover the dislocation.

The plaintiff sued his writ in the High Court on April 25th,

...days after he left the defendant's care, consequently pleaded the statute. The court judge held that it was not a case of "a continuance of injury or damage" beyond October 15th, but he further held that the time limited by the statute did not begin to run until the cause of action arose, that no cause of action arose until damage resulted to the plaintiff, that no damage resulted until such time as plaintiff, if properly treated, would have been fit to return to work, which would have been less than six months before action was brought. He therefore gave judgment for the plaintiff.

The defendant appealed, and the Divisional Court (consisting of Salter and Swift, JJ.) held that the damage began to accrue from the date of the neglect or default, and that the action was out of time. The plaintiff then appealed.

Judgement of Banks, L.J.

Lord Justice Banks in his judgement, said: In this case the plaintiff brought an action against a medical man claiming damages for negligent treatment. The facts, so far as it is material to state them are that the plaintiff was knocked down by a motor car and was injured. He was removed to the hospital, where he was attended by the defendant. As found by the county court judge, the defendant was negligent in failing to diagnose what the plaintiff was suffering from. Had he done so the plaintiff would have recovered within a short period of time. As it was he remained in the hospital for some time and then, being dissatisfied with the treatment, he left, and submitted himself to other medical men, who advised an operation, which necessarily resulted in the permanent shortening of one leg. The action was not commenced within six months of the plaintiff leaving the hospital and ceasing to be attended by the defendant. The defendant pleaded the Public Authorities Protection Act, 1893. It was admitted for the plaintiff that the Act applied but it was contended that the action was not, in the circumstances, barred. It is obvious from a perusal of the schedule containing the enactments repealed, which go back as far as the reign of Queen Elizabeth that the Legislature intended in the case of actions against public authorities not only to substitute one time limit for all existing time limits, but by adopting a new definition of what constituted that limit to modify the existing law upon the subject. If it were open to this court to put its own construction on the language used, it would be necessary to consider very carefully what the construction should be and to discuss the various authorities which have been cited to day. As far as this court is concerned it must accept the construction put upon the language of the section in *Carey v. Mayor of Bermondsey* (67 J.P., 111). That was an action tried before Mr Justice Channell. The plaintiff had been injured by falling over a projection in the road which had been put there by the negligence of the defendants' servants. The fall and the injury occurred more than six months before action was brought. At the time the action was brought, the plaintiff was still suffering from the injury. The defendants pleaded the statute. The contention by the plaintiff's counsel was that the injury or damage to the plaintiff had not ceased when she brought her action, that the words of the section must be given their ordinary meaning, and that if the injury ceased immediately after the accident the damage still continued. Mr Justice Channell without calling on the counsel for the defendants, decided in their favour holding, in effect that the only case in which the time limit did not apply after the expiration of six months from the date of the neglect or default was where there was a continuing cause of action. This decision was affirmed in the Court of Appeal consisting of Lord Halsbury L.C. and Lord Alverstone L.C.J. (67 J.P., 44 and 20 T.L.R. 2). Counsel for the defendants urged that at the time of action brought the plaintiff was still suffering from the consequences of the defendants' negligence and that so long as she was suffering there was a continuance of the injury or damage. Lord Halsbury dealt with the argument as follows. He said: 'The language of the section was reasonably plain, and it was manifest that the continuance of the injury or damage meant the continuance of the act which caused the damage. It was not unreasonable to say that if there was a continuance of an act causing damage the injured person should live an action at any time within six months of the ceasing of the act complained of. But that was wholly inapplicable to such cases as the one before them where there was no continuance of the act complained of and where the only suggestion was that, in consequence of that negligent act the victim was not such a good man as he was before. Words had to receive a reasonable interpretation. The report in this case appears only in the *Justice of the Peace* and in the *Times Law Reports*. Whatever may be the proper inference to be drawn from that fact, the language used by the Lord Chancellor is unmistakably plain and this Court must accept it and apply it. I cannot distinguish the facts of this case from the facts in *Carey's* case and I am unable to agree with the view taken by the learned county court judge of a distinction which was suggested to him. The contention took this form: but for the defendants' negligence, it was said, the plaintiff would only have been laid up for so many weeks. The damage he suffered from loss of earning power during these weeks is attributable to the motor. The plaintiff's loss or damage due to the defendant's negligence only dates from the time when but for that negligence he would have regained his earning power. With every desire to assist the plaintiff I am unable to accept this contention and I think that the decision of the Divisional Court was right and this appeal must be dismissed with costs.'

Lord Justice Scrutton and Lord Justice Atkin delivered judgement to the same effect.

Obituary

We regret to record the death of Mr FRANK CROSS BARDSEY, of Wimpole Street and Salisbury, which occurred after a short illness on October 12th, at the age of 59. Mr Bardsley received his education at the University of Cambridge, where he graduated B.A. in 1888, and University College, London. He obtained the L.S.A. in 1891, and the degrees of M.A., M.B., B.Ch. Camb. in 1896. He was well known in Salisbury for his active association with the infirmary, to which he was appointed ophthalmic surgeon in 1912. He was also ophthalmic surgeon to the school clinic of the city. His London appointments included those of ophthalmic surgeon to the Willesden Hospital and the British Hospital for Incurables, chief clinical assistant to the Royal London Ophthalmic Hospital, and lecturer to the Church Missionary College, Islington. He contributed numerous articles on ophthalmological subjects to the *British Journal of Ophthalmology* and the *Transactions of the Ophthalmological Society*. Mr Bardsley was a member of the British Medical Association. He leaves a widow.

The following well known foreign laryngologists have recently died: Dr Carlo Biaggi of Milan (aged 62), Professor Capart of Brussels (aged 80), Professor Schuiffers of Liege (aged 77), and Dr Chetellier of Paris (aged 70).

Medical News.

MR HARVEY HADDEN of Berkeley Square, London, has contributed £1,000 to the endowment fund of the James Mackenzie Institute for Clinical Research, St Andrews. The county of Perth has contributed £7,500 as a tribute to the late Sir James Mackenzie, the founder of the Institute, who was born in that county.

INVITATIONS have been issued for the winter livery dinner of the Society of Apothecaries of London to be held in the Society's Hall, Blackfriars, on the evening of Tuesday, December 15th.

THE Lady Priestley Memorial Lecture before the National Health Society will be delivered by Dr Robert Hutchison at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., on Thursday, December 3rd, at 5 p.m. The subject of the lecture will be diet in childhood and adolescence.

ON November 30th, at 5.30 p.m., Mr Herbert Tilley will lecture for the Fellowship of Medicine on tuberculosis of the larynx in the lecture hall of the Medical Society of London, 11, Chandos Street, W.1, the lecture is free to all members of the medical profession. From November 30th to December 13th the Infants Hospital will hold a special afternoon course, with the exception of Sunday, when a morning visit will be paid to the Charles Ian Clinic. Lectures and demonstrations will be given by members of the staff, and visits made to the Nursery Training School, Hampstead Garden Suburb, and the Home for Blind Babies, Chorley Wood. The Hampstead General Hospital will hold a late afternoon course from December 7th to 19th covering medicine, surgery, and the special departments. At the Blackfriars Hospital for Diseases of the Skin a course in dermatology will be given from December 7th to 19th, instruction will be given in the out-patient department and venereal clinics twice weekly. The following special courses are announced for January: Medicine, surgery, and the specialties at the Prince of Wales's General Hospital, cardiology at the National Hospital for Diseases of the Heart, diseases of children at the Queen's Hospital, infectious fevers at the North Eastern Hospital, neurology at the West End Hospital for Nervous Diseases, and psychobiological medicine at the Bethlem Royal Hospital. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the Secretary to the Fellowship, 1, Wimpole Street, W.1.

A THREE months' course of lectures and demonstrations in hospital administration will be given by the medical superintendent (Dr E. W. Goodall) at the North Western Hospital of the Metropolitan Asylums Board, Lawn Road, Hampstead, N.W., on Mondays and Thursdays at 4.45 p.m., and alternate Saturdays at 10.30 a.m., commencing on Thursday, January 7th, 1926. The fee for the course, which complies with the requirements of the revised regulations of the General Medical Council, is £4 4s.

At a general meeting of the Röntgen Society at the British Institute of Radiology (32 Welbeck Street London, W 1), to be held on Tuesday next at 8.15 p.m., the second Röntgen Award will be made to Dr. Robert Knox for his paper on the investigation of the movements of the heart by the use of the slit diaphragm and the moving film. Papers will be read on microscopical for induction coils, by Mr. R. J. Stephenson of University College, Reading, and on oscillographic observations on induction coils and transformers, by Dr. L. A. Owen of the National Physical Laboratory.

Owing to the death of Queen Alexandra the dinner in aid of the National Association for the Prevention of Tuberculosis, which had been arranged for December 9th, has been indefinitely postponed.

AMONG the recently elected Fellows of the Royal Sanitary Institute are Dr. G. W. Neild Joseph (M.O.H. Warrington), Dr. A. B. McMaster (M.O.H. Dover), Dr. Frank Robinson (M.O.H. Crumlin, Leicestershire), Lieutenant-Colonel B. J. Singh, Director of the Medical and Sanitary Department, Hyderabad, and Dr. D. L. Thomas (M.O.H. Stepney).

THE Tolmorden Medical Society has made a donation of 10 guineas to Lpsom College.

THE Umberto I prize of the Rizzoli Orthopaedic Institute in Bologna for 1924 has been awarded to Dr. Alaziz Farhas of Budapest for his essay on the etiology and pathology of the scolioses.

DR. COLSON of Durant has been elected president of the Belgian Royal Academy of Medicine for 1926, with Professor Guillaumeaerts of Brussels and Professor Friederich of Liege as vice presidents.

THERF has recently been a great increase in the number of local outbreaks of typhoid fever in Germany. During the first thirty weeks of the year 5,903 cases were notified throughout the country, as compared with 5,356, 5,273, and 5,996 in the corresponding periods of 1922, 1923, and 1924.

THE incidence of small pox in Switzerland of recent years is shown by the following figures: 1915-20, 14 cases; 1921, 595; 1922, 1,159; 1923, 2,445; 1924, 1,245; January to May, 1925, 156.

ACCORDING to the *Deutsche medizinische Hochschrift* there has recently been an outbreak of swimming bath conjunctivitis in several schools in Germany.

THE von Graefe prize of the German Ophthalmological Society is to be divided equally between Professor Seidel of Heidelberg and Professor von Szily of Münster.

IN the Bulletin for 1925 of the Ophthalmological Society of Egypt, which was founded in 1902, a report is given of the annual meeting in Cairo on March 6th, together with the clinical papers read at it.

THE birth rate in Prussia, which was 27.7 per 1,000 inhabitants in 1913, fell to 26.1 in 1921, 23.7 in 1922, 21.7 in 1923 and 21.1 in 1924. In Bavaria 207,457 children were born in 1913, 177,943 in 1923, and 171,951 in 1924.

THE Académie de Médecine of Paris has been left a legacy of 50,000 francs by Madame Alphonsine Matilde Maure for founding a biennial prize, to be known as the "Prix Docteur Jules Brault," for the best work on exotic pathology or dermatology.

THE engineer, Dr. G. Schmaltz, has recently been made an honorary doctor of medicine at the Frankfurt Medical Faculty for his work on the physiology of the labyrinth.

DR. CHARLES MAYO has been nominated officer of the Legion of Honour.

AS a memorial to the Rev. E. H. Mosse of St. Paul's, Covent Garden, who was killed in 1918 during an air raid on London, a mission hospital was erected at Ta Tsung Lu, a city in the Shan Si Province of Northern China, inhabited by a primitive and intensely conservative population. The first outpatients were received at the end of 1922, and accommodation was provided for inpatients in December, 1923. The first annual report (issued by the S. P. G.) indicates gratifying progress in the face of great difficulties. The number of inpatients during the first year was 396, and of outpatients 2,464. Venereal disease is very rife and mixed infections of tubercle and syphilis are frequent. The commonest eye affection is trachoma, and copper sulphate has been replaced by zinc sulphate with advantage. Synechiae are rare, though in the corneal region, regions of North India they are very common. Xerophthalmia is often encountered but has rarely yielded to cod liver oil and a well balanced diet. No cases of malaria, filaria, or leprosy have been dealt with, but ticks and osteomyelitis are common and severe, possibly, it is suggested, owing to the considerable amount of oatmeal eaten in the district. Although no acute rheumatism has been reported, yet valvular disease of the heart occurs in young subjects, and many cases show lesions of the aortic valve despite freedom from syphilis.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notices to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring PEPHINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are: **MUSEUM 9361** (9.30 a.m. to 5 p.m.) and **9363** (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are: **EDITOR of the British Medical Journal, Antiology Westcent London**.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) *Antiology Westcent London*.

MEDICAL SECRETARY *Mediscien Westcent London*.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams: *Bacillus Dublin* telephone 4737 Dublin) and of the Scottish Office 6 Drumshugh Gardens, Edinburgh (telegrams: *Associ e, Edinburgh* telephone 4361 Central).

QUERIES AND ANSWERS

"THERF"—The condition was probably due in the main to the local anaesthetic associated with malnutrition and emotional disturbance.

BAGGI ETALINS

"J. G. B." asks for information as to the pathology of "big" eyelids met with in apparently healthy individuals of middle age.

CRACKED NIPPLES

"E. K." writes: If "Medicins" (*JOURNAL* November 14th p. 927) will provide his patient with cracked nipples with Wansborough nipple shields lead to be worn continuously he will have no more trouble with this condition. No drugs are required. The shields have served me well in scores of cases.

TREATMENT OF ASTHMA

In reply to the inquiry published in the *JOURNAL* on November 14th (p. 927), Dr. J. P. FINE (Leamington Spa) writes that he has found nothing so successful as an early hypodermic injection of morphine (gr. 1 especially if it induces sickness). He also recommends a trial of euphonia. Inhalation he found usually relieved difficult breathing and oppressive headache. According to Martindale's *Extra Pharmacopoeia*, euphonia contains caffeine and iodine and it is taken by the mouth, 1 to 4 drachms daily before meals.

INCOME TAX

Expenses on Entering a Practice

"A. Y. Z." has recently entered a practice and has had to pay a considerable sum for legal agreements. Is he entitled to any allowance for this or for the cost of ledgers and similar books?

* * The broad distinction with regard to such expenditure is that between capital outlay and sums expended in the ordinary course of professional work. The legal expenses—if in connexion with the partnership agreement—are not allowable, they were incurred by "A. Y. Z." in entering the practice not in carrying on his work but we consider that the cost of the books of record should be allowed. The latter expense would, we believe, be allowed in the case of a person setting up in business and in regard such sums—which after all are expended merely in the purchase of professional stationery—as representing capital outlay seems to be an unreasonable straining of the principle.

Car Transactions

"H. F. W." bought a second hand car in March 1924 for £85, in November of the same year he sold it for £30 and bought a new car of another make for £263. How much is he entitled to deduct?

* * Of the net expenditure of £263-£50=£213 £85 was incurred in replacing the old car and that amount can be charged as a professional expense of the year in which the expenditure was incurred. The £213 forms the basis of the depreciation allowance to be claimed from the gross (average) assessment, the allowance will be £213 at 15 per cent =£32. The reply in a former issue to which "H. F. W." refers was not based directly on any particular case but was in accordance with the generally recognized principles of law.

URTICARIA
DR. CURRIE (Wokingham) writes in reply to "N. L."
 "I would refer him to Dr. Henry
 [illegible] and desensitization in skin
 [illegible] JOURNAL, October 24th 1925], where
 [illegible] injections is described. Since
 [illegible] per I have treated in this way a
 similar case of six months duration, and already after four
 injections there is remarkable improvement."

R. W. L. WAINWRIGHT (Henley on Thames) writes to advise
 "N. L." to try the intravenous injection of afebril, a calcium
 preparation sold by Knoll. Our correspondent has tested it in
 two severe cases in both instances with success. He offers to
 give "N. L." further information if asked.

R. H. M. WALKER (Harrow) writes: "I would suggest that the
 most useful treatment consists of a course of 6 to 12 injections of
 1 c.c. of colloidal calcium (Crookes). Should this fail it might be
 well to have a bacteriological examination of the throat and
 bowel made. Some cases of auto-intoxication particularly from
 a streptococcal infection appear to be marked by an instability
 of the vasomotor system and are considerably benefited by local
 treatment by alimentary antiseptics and a course of autogenous
 vaccines. Should there be any fibrositis in the subcutaneous
 tissues massage is, I think, an important means of treatment in
 addition to the above."

R. J. BARKER SMITH (London) writes: "I strongly recommend
 "N. L." to treat his patient as a potential diabetic and to
 examine the urine for so small a quantity of sugar as 2 per 1,000.
 He should take notice of the specific gravity of the sample sent,
 and examine several samples, he may possibly find also a
 diabetic in the family. Should "N. L." take 1 c.c. of L. H. King's
 solution he may even miss the yellowish red reaction of sugar,
 the contents of the tube brown. One drop of urine on a silica
 crucible lid or on a small strip of aluminium sheet held by a
 spring linen peg carefully evaporated to an extract and the
 extract then charred thoroughly or carbonized plunge the strip
 into cold water and rub with soft finger tip the sugar char
 remains. It is the best of tests. Give diaphoretics."

LEAD SALTS IN CANCER

R. GEORGE C. BELCHER (Birmingham) writes: "Some years ago,
 when using lead as a haemostatic in a case of malignant growth,
 to my surprise it had the effect of arresting the advance of the
 tumour, and from that time to this I have always used lead
 acetate internally for inoperable cases of cancer sometimes
 with very marked improvement. What the effect may be on
 the cells I cannot say, but patients diagnosed by competent
 surgeons as having inoperable growths are alive and well to day,
 whether the growth is in abeyance or entirely destroyed there
 is no symptom at the present time and this in some cases after
 several years. The salt has to be administered in heroic doses
 to get the patient under its toxic influence—one grain and a half
 daily for the first week, and then the same dose twice a day until
 the patient becomes a pasty yellow which takes some weeks
 it is then dropped entirely and no treatment applied except for
 other symptoms. It is surprising how in time if the patients
 recover they lose this condition of lead cachexia and the skin
 becomes pink and normal. Of course every case does not respond.
 Growths of the neck do not seem to be affected by it."

RHEUMATOID ARTHRITIS

MR. W. VERNER FURLONG (Dublin) writes with reference to the
 letter signed "A. Vietum" (JOURNAL, November 14th, p. 922) to
 suggest the use of iodolysin, and mentions a case of advanced
 rheumatoid arthritis in which administration of the drug
 (20 drops in water twice daily) proved very beneficial. Iodolysin,
 according to Martindale's *Letra Pharmacopoeia* contains 43 per
 cent of thiosamin and 47 per cent of iodine. It is there noted
 that Sir Thomas Horder has spoken well of the drug adminis-
 tered in pills equivalent to 7½ grains of potassium iodide, two to
 six pills are to be taken daily after food. The combination was
 found to be tolerated and to be less depressing than potassium
 iodide.

APPARENT STILLBIRTH RECOVERY

MR. W. L. BLACKFORD (Cheslyn Hay, Staffordshire) writes:
 "On August 14th 1925, I delivered a woman a different forceps
 case of a full term male child weighing 9½ lb. She had a
 small round pelvis and the presentation was occipito posterior,
 it was turned to left occipito anterior after considerable effort.
 A small perineal tear was sutured. When delivered the child was
 very blue, no respirations were present and no heart beats were
 audible to the ear placed near the child's bare chest. For
 thirty to sixty seconds I attempted artificial respiration without
 success. The heart was still silent. I took up 1½ c.c. of
 pituitrin into a 1 c.c. hypodermic syringe and having cleaned
 and sterilized the left chest with methylated spirit I plunged
 the needle through an intercostal space into where I considered
 the heart to be. The needle went in half an inch to outside of
 the left edge of the sternum and was in the fourth left intercostal
 space. I then began artificial respiration again by Marshall Hall's
 method. About one to two minutes later I again listened to the
 heart and heard it beating loudly and steadily at about forty to
 fifty beats a minute. I then placed the child in a hot bath and
 attempted Silver's method. The child still did not breathe,

so I commenced mouth to mouth respiration through a clean
 napkin. This I kept up for about thirty to forty minutes, when
 the child gave a sighing expiration voluntarily. I redoubled my
 efforts, and was rewarded by the slow onset of normal respiration
 at the end of an hour from birth. I then gave a hypodermic
 injection of strychnine, 1/100 grain, and put the infant to bed
 with hot bottles around it. When I left it the child was still
 very blue but was breathing fairly easily. The next morning it
 was pink and warm and apparently normal. I, however, con-
 tinued to give strychnine (by the mouth). The question I should
 like to ask physiologists and pharmacologists is: Do they con-
 sider that pituitrin is capable of stimulating cardiac muscle to
 commence to contract or would it be more proper to look upon
 the case as one where the heart was beating very, very faintly,
 so as to be inaudible, and that the pituitrin reinforced the heart
 contractions already present? I must express my appreciation
 of the midwife Nurse Price. Her aid was invaluable, and
 without her assistance I might not have succeeded."

PERSIAN OIL

THE Anglo Persian Oil Company dates back to 1901, when Mr
 W. K. D'Arcy obtained a concession from the Shah of Persia
 The crude oil is brought down in pipe lines across the desert to
 the coast and shipped from there to Llandarey South Wales,
 where it is refined. The British Petroleum Company which is
 the distributing organization in this country has sent us a fello
 pamphlet containing many excellent drawings of life in ancient
 Persia and primitive Persia of to day, and giving briefly
 the story of the petroleum before it becomes the "B.P." petrol
 largely used with satisfaction by motorists. Copies of the pam-
 phlet can be obtained on application to the British Petroleum
 Company Britannia House, Moorgate Street, L.C. 2

ASSISTANTS STARTING IN RIVALRY TO PRINCIPALS

A MEMBER residing in Glasgow writes to warn practitioners to
 require every assistant to sign the usual bond not to begin in-
 dependent practice within a specified distance of his own resi-
 dence. In three recent instances within his own knowledge (all
 of them women practitioners) the assistant refused to sign the
 bond after being with the principal for some time. He goes on
 far as to suggest that such cases might be brought to the notice
 of the General Medical Council on the ground of indirect
 canvassing.

CANCER AND DIET

The possible association of cancer with some irregularity of diet
 has for long been the subject of thought and inquiry. Dr M.
 Hindhede of Copenhagen has published the results of a careful
 study of cancer statistics from this point of view in the *Acta
 Medica Scandinavica* for October 24th. He finds that the death
 rate from cancer is higher in Denmark than in any other
 country and that the disease is increasing rapidly. In 1900 the
 rate was 120 per 100,000 inhabitants in Danish towns, while
 Sweden showed a death rate of 100 to 108, the corresponding
 figures in London were 112 in Paris 111, in New York 77, and in
 Calcutta 12. Comparison of different classes of the community
 seems to him to indicate some connexion between cancer and
 overfeeding during the time of war raising the cancer
 mortality in Denmark fell to the level of that in Sweden.
 Hindhede thinks that English statistics indicate a higher inci-
 dence of cancer in those callings whose members indulge in
 abundant food and alcohol, and infers from this that a high
 protein standard is not only unnecessary but actually harmful.
 He concludes that among the main causes of cancer must be
 reckoned irritation of the alimentary canal from the consumption
 of decayed, strongly salted and spiced foods the use of alcohol
 and tobacco, and over nourishment by varied savoury foods with
 an excessive protein content. It will be remembered that
 Dr Hindhede read a paper on alcohol restriction and mortality
 before the Section of Medical Sociology at the Annual Meeting of
 the British Medical Association in Glasgow in 1922 (JOURNAL,
 1922, ii p. 248).

A DISCLAIMER

SIR JAMES DUNDAS GRANT (London W.1) writes: "My attention has
 been called to the issue of a leaflet announcing a lecture which
 I was recently invited to give to members of the Young Men's
 Christian Association, at their hall in Aldersgate Street. On
 hearing of it I at once telephoned to the secretary that no further
 distribution should take place. I need hardly say it was issued
 without my knowledge."

ROAD PLANS

THE Dunlop Rubber Company Ltd. has now issued the sixth
 volume in its series of pictorial road plans, *On the Road*,
 published by Ed J. Barrow and Co. Ltd. of Cheltenham,
 price 6d. This describes for the benefit of motorists, in thirty five
 strip maps the 394 miles of the Great North Road which
 link together London and Edinburgh.

CORRECTION

We regret that in last week's issue lines 7 and 8 in column 1 of
 page 939 were by some inadvertence transposed.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges
 and of vacant resident and other appointments at hospitals
 will be found at pages 40, 41, 44 and 45 of our advertisement
 columns and advertisements as to practitioners, assistantships,
 and locum tenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement
 columns appears in the Supplement at pages 187 and 188.

A British Medical Association Lecture ON THE SYMPTOMS AND SIGNS OF ABDOMINAL CRISES IN CHILDREN.*

BY

JOSEPH E. ADAMS, M.S., F.R.C.S.,

SENIOR SURGEON, EAST LONDON HOSPITAL FOR CHILDREN,
SURGEON TO ST. THOMAS'S HOSPITAL

My definition of an abdominal crisis is a condition which demands the mind of a physician to diagnose and the hands of a surgeon to treat. Fortunately is the man who can exercise both these faculties, and till more fortunate the patient who calls him into consultation. Moynihan has said that the abdominal surgeon is a physician who is condemned to precise surgery. The double role, then, is not an impossibility. In these days acute abdominal diseases are no less of a mystery than they were, and it is recognized that we ought, as a rule, to know the nature of the lesion before we open the abdomen. Nevertheless, the sick child will always present a particularly difficult problem, and I have the greatest sympathy with "The Doctor" in that well known picture by Sir Luke Fildes, for he obviously has not the faintest idea what is the matter with the child. It is more than half the battle to know when to open the abdomen, and the man who makes the fewest mistakes in diagnosis deserves the highest praise, for he will run the smallest risks with his patients' lives. This is, indeed, the counter with which we gamble, for abdominal exploration in sick children is a thing to be avoided. Whatever is done must be done quickly. Children are not good subjects for abdominal surgery, and much time is lost if the diagnosis is not made until the abdomen is opened.

For these reasons I propose to endeavour to put this subject before you from the purely clinical standpoint. The materials at our disposal will be the history of the illness and the patient, coupled with our book learning and our experience. These last two are perhaps the more important, for diagnosis is largely a question of assessing the odds, and from books and experience we can learn what the odds are. The history of the case and the evidence of the patient are notoriously deficient in the case of children, and in hospital cases this help is merged to a degree.

The three steps in diagnosis are suspicion, probability, certainty. If a young child is brought to hospital with a history of passing blood and mucus per anum we naturally suspect intussusception. If inquiry proves that the onset was sudden and the trouble started with a fit of screaming in which the child was doubled up, it makes intussusception the probable diagnosis. If examination reveals a sausage-shaped abdominal tumour which can be rolled up and down, and still further if the apex of the intussusceptum can be felt by the rectum, all doubt is at an end and the diagnosis becomes certain. The history consists of two parts—first, the predominant symptom or chief complaint, and secondly, the progress of events following the onset. As we are dealing to-night with acute abdominal disease, suddenness of onset is of the essence of the contract. The previous health may or may not have been good—that will be ascertained with the detailed history, but the starting point of our discussion is an acute onset suggestive of abdominal disease. What, then, are the cardinal symptoms of such disease? Abdominal pain, vomiting, alteration of the bowels from their normal phase of activity. The physical signs are alteration of abdominal contour, rigidity of abdominal muscles, and the presence of an abdominal tumour or mass. All other symptoms and signs are supplementary or complementary to these in a positive or negative sense, though I must add that many examination may by itself give the whole clue to the correct diagnosis. I may perhaps remark here

that to make a diagnosis of an abdominal crisis without knowing the state of the mind is not possible.

The child and the adult differ, but the difference is exaggerated, though it is true that the field for diagnosis in children is limited by the fact that certain lesions are almost unknown in the first decade of life. Perforation of a gastric or duodenal ulcer and acute cholecystitis will at once occur to you as belonging to this almost unknown category. There are, however, examples of diseases very rare in adults but common in children. I need only mention intussusception and tabes mesenterica. Our book learning or personal experience is of the greatest value in this connection, for when we approach the patient with an abdominal crisis we must be aware of all the possibilities and weigh them up as against the probabilities suggested by the history of the case. Another point of importance is the fact that specific fevers not infrequently have a pseudo-abdominal onset, and we must be particularly careful to bear in mind that when the history of the case is scanty we may easily mistake lesions above the diaphragm for those of the abdomen itself. Lesions which simulate acute abdominal disease must first be eliminated from the diagnosis. This may be done by instinct in many cases, but in others a conscious reasoning process is necessary, and oftentimes a very minute examination of the patient is required in order to rule them out. Perhaps we cannot do better than pass rapidly in review those extra-abdominal diseases which are likely to prove traps for the unwary diagnostician in the case of young children.

THE SPECIFIC FEVERS

1 Scarlet Fever

Vomiting is common at the onset, and if it is repeated and severe, as it sometimes is, abdominal disease, even peritonitis, may be simulated. Abdominal pain is sometimes complained of. The existence of a sore throat, high temperature, and very rapid pulse at the onset put one on the right track. If the disease is seen later the characteristic rash should solve the problem.

2 Enteric Fever

This can hardly be described as an extra-abdominal disease, and at its onset it is sometimes remarkably like an attack of appendicitis. If the abdominal pain and tenderness be almost confined to the right iliac fossa there may be the greatest difficulty, but it is important to remember that the pulse in typhoid is slow in proportion to the temperature, there is apt to be mental confusion or torpor, headache, and the abdomen is tumid without reflex rigidity. A leucopenia is present rather than a leucocytosis. Examination of the stools by culture, or of the blood in an ox-bile medium, will go far to establish the diagnosis in the days before a Widal reaction will be a reliable guide. A typhoid perforation certainly comes under the heading of an abdominal crisis, one of the most serious, but this disaster rarely occurs before the third week of the disease, and thus the diagnosis is made easier. This complication is usually associated with a sharp fall of temperature, severe abdominal pain, and acceleration of the pulse rate. Local tenderness and rigidity are the leading physical signs.

3 Mumps

Metastatic pancreatitis is well known as a complication of mumps, but as far as I am aware it rarely occurs in children, and the condition of the salivary glands is always a predominant feature of the disease.

4 Influenza

The gastro-intestinal type of influenza with colicky pains, diarrhoea, and vomiting does call for careful scrutiny. The pulse is apt to be slow and the temperature high. Pains in the back and limbs, together with orbital headache and prostration, are especial features. These are often associated with the usual symptoms of respiratory catarrh.

INTRATHORACIC DISEASES

1 Pneumonia

Of all the lesions above the diaphragm this is most likely to lead to error. Most surgeons of experience have to confess to having removed the appendix for

Let it be in the most often rises, and it has declined to operate when a surgeon or a medical colleague peritonitis nearly always have an on ratio and the *via nasi* may be active with the absence of sputum, and but little with pneumonia in children, accounts for the difficulty. It must be remembered that pneumonia in children is rarely of the true lobar variety, and the physical signs will be those of bronchopneumonia. Very rapid respiration should at once suggest the true nature of the disease, even if vomiting has occurred and abdominal pain is complained of. The temperature is a poor guide, but a high respiration pulse ratio is characteristic of pneumonia. The patient with lung disease likes to lie on his side, the peritonitic patient prefers to lie on his back with the thighs flexed on the abdomen. The flushed face, labial herpes, and very active *via nasi* are strongly suggestive of pneumonia. If there are signs of consolidation of the lung and the rigidity of the abdomen on palpation is intermittent, it is pretty certain that the real lesion is above the diaphragm, and I cannot lay too much emphasis on this absence of true and permanent rigidity, for it has enabled me to avoid laparotomy on several occasions. Such rigidity as is secondary to lung disease is voluntary rather than reflex.

It must, however, be remembered that peritonitis may be a complication of pneumonia. If it is a late one—and it most frequently is—the diagnosis is not difficult. But it may occur early in the disease, and evidence of fluid in the abdomen may be proof of a spread below the diaphragm.

2 Pleurisy and Empyema

The physical signs in cases of pleurisy, which may or may not be going on to the stage of pus formation, are sufficiently clear to enable a careful clinician to avoid mistakes, provided he thinks of such a condition. This is commonly accompanied by some voluntary rigidity of the abdominal muscles, but between the attacks of abdominal pain, which may be somewhat pronounced, there is full relaxation. The activity of the *via nasi* and rapidity of respiration should suggest a thoracic lesion. As regards fiction rub it is true that such a sound may be heard low down in the axilla as the result of peritonitis alone, whereas that due to pleural inflammation is usually audible at the base of the lung posteriorly. This is also, of course, the likely position for the dullness on percussion.

3 Pericarditis

This disease is apt to cause arrest of the movements of the diaphragm, and therefore the abdomen tends to become immobile. Such cases may easily masquerade as acute abdominal disease, since epigastric pain may be complained of and vomiting is sometimes severe. However, in cases of doubt a period of watching together with careful examination of the cardiac area, will probably make the diagnosis clear.

4 Heart Disease

Acute dilatation may be deceptive, but the urgent dyspnoea, with cyanosis and very rapid pulse, together with enlargement of the cardiac dullness should point away from the abdomen. Chronic disease of the heart is well known to cause vomiting, and abdominal pain may be complained of. Infection of the spleen or kidney may complicate matters but a careful examination of the heart will reveal signs of a positive character.

NERVOUS DISEASES

1 Intracranial Lesions

Tumour, abscess of brain, and meningitis are all causes of vomiting, and the vomiting may be incessant, even resembling that of intestinal obstruction. Tuberculous meningitis is particularly likely to be confused with abdominal disease. Vomiting, obstinate constipation, and

abdominal rigidity are its especial features. The abdominal wall, however, is likely to be retracted, a condition which is hardly ever associated with abdominal disease, except high obstruction or a very recent perforation. This is the so-called *carinate abdomen*, which in a very fretful child, who screams whenever he is touched, goes far to make up the picture of tuberculous meningitis, though the symptoms may be suggestive of abdominal disease. It is true that tuberculous peritonitis may sometimes be present, but this usually leads to a tumid abdomen. Further, perforation of a tuberculous ulcer may occur and the recognition of all these manifestations of tuberculosis would require a perfect genius to diagnose correctly. Most of these intracranial diseases lead to headache and coma in some degree, and if careful examination of the nervous system is made mistakes will rarely arise.

2 Functional Disease

Anorexia nervosa may go to such a pitch that the repeated vomiting resembles that of obstruction, but it is hardly likely to reach that stage in children.

TOXIC CONDITIONS

1 Cyclical Vomiting and Acetonaemia

The former term has rather gone out of fashion and the presence of acetone and ketones in the blood is recognized as responsible for the repeated vomiting which occurs in these cases. It is, indeed, a vicious circle disease, and children are its commonest victims. In a first attack the resemblance to an acute abdominal lesion, particularly appendicitis, is very close. The onset may be severe, with initial abdominal pain and early vomiting. There is often abdominal distension and tenderness, mostly due to the repeated vomiting. If the caecum is distended there will probably be tenderness in the right iliac fossa, and therefore the diagnosis of appendicitis will suggest itself. The appearance of the child, however, should help. The eyes are sunken, with dark rings beneath them, the face is pallid, and the lips rather bright in colour. There is lethargy, with restlessness, and true sleep is not obtained. The tongue is coated and the breath—the most characteristic sign—is heavy, with a sweetish odour. This may pervade the room, if the child is not seen in a hospital ward. Listlessness, thirst, and absence of desire for food are notable symptoms, and probably there will be a history of constipation, with lack of energy, for some days before the vomiting has occurred. As the disease progresses coma and delirium make their appearance. The diagnosis, of course, depends on a careful urinary analysis, and, if time permits, a chemical examination of the blood. It must be remembered, however, that acetonaemia is a result of repeated vomiting from any cause, and therefore one must be quite sure that there are no positive signs of the acute abdomen before resting satisfied with the diagnosis of primary acetonaemia. The question is one of degree, and if the acetone overshadows the other aspects of the case it is clear that this must receive immediate attention. Without going into the details of treatment I may remark that the response, even in grave cases, is most prompt.

2 Uræmia

It is well known that gastro-intestinal symptoms may dominate the clinical picture in uræmia, but I think this is far more likely to arise in adults than in children. Paucity of urine and its high albumin content should settle the diagnosis.

OTHER DISEASES

1 Intestinal Colic

Several times have I had difficulty in diagnosing between "green apples" and appendicitis. Many errors in diet may give rise to irregular and excessive peristalsis. Severe gripping pains with intermittent abdominal rigidity and some degree of collapse are met with, but sooner or later diarrhoea is manifest, and thus, together with a careful history, will usually prevent erroneous diagnosis. The pain of simple colic is nearly always relieved by pressure, and thus a peritoneal lesion is differentiated from it.

2 Food Poisoning

This, as distinct from unsuitable or indigestible food, is associated with vomiting and early diarrhoea, and collapse out of all proportion to the degree of abdominal pain.

3 Ilac Abscess

Many lesions may be responsible for such an abscess, and if it is situated in the right iliac fossa it may easily simulate an appendix abscess. The peritoneal physical signs, even if vomiting has occurred, will not be found to substantiate the false diagnosis, and investigation should lead to the discovery of the source of the pus, whether it be bone, joint, or glands. Probably the last is the most frequent source of doubt, but the low position of the abscess and its proximity to the pelvic brim are signs to differentiate it from an appendix abscess. Inspection of the leg will probably show a boil or septic cutaneous lesion. Flexion of the right hip is met with in appendix abscesses. Similarly a psoas abscess may resemble an appendicular one, but such symptoms as are present are rarely acute.

4 Henoch's Purpura

A haemorrhagic diathesis is easily recognized if it presents external signs, such as bleeding from the gum and petechial eruptions. The disease, however, may affect the intestine and cause severe abdominal pain, vomiting, and the passage of blood and mucus per anum, and yet no spots may be seen nor evidence of bleeding elsewhere. Obviously such cases must at first sight resemble intussusception, and it may be that the correct diagnosis can only be made by the absence of the abdominal tumour without which an intussusception cannot really be diagnosed. In purpura it is common for vomiting to precede pain, in intussusception sudden and severe abdominal pain is almost invariably the initial symptom. Passage of blood by the bowel is not constant in Henoch's purpura, and probably this depends on the site of the intramural effusion of the bowel—the lower down it occurs the more likely is there to be bleeding per anum. If bleeding from the gums is present, and especially if reddish-purple spots are seen over the body, the diagnosis becomes easy, but the disease is on the whole a rare one. Of its etiology we are woefully ignorant. Some fever is common as well as abdominal tenderness. A tumour has been observed, and there are cases where it appears that intussusception has followed on Henoch's purpura. Evidence of such a sequence should be very conclusive before abdominal exploration is carried out.

I am afraid I may have wearied you with what must be regarded as an introduction to my main thesis, but in reality the mind of the clinician must contain thoughts about all these possible conditions. Consciously or unconsciously he must weigh them up, although the chief complaint and the leading signs in the case may enable him to discard them all. He then reaches the next phase, which is that of differential diagnosis among those acute abdominal states which demand operative treatment. He is convinced that an abdominal crisis is before him, but which is it? If abdominal diagnosis were degraded to the level of a guessing competition he would, in adults at any rate, plump for the appendix every time, for he would be right in 70 per cent of the cases. In children, however, the preponderance of intussusception and the prevalence of trouble due to tuberculous glands bring down the chances of appendicitis to about even odds. Everyone seeks to be right more often than wrong, and therefore we must apply our minds carefully to the diagnosis. Much depends on its accuracy, for if we know before opening the abdomen what has to be done we can certainly do it quicker, and, above all, we can operate through the most suitable incision.

One word with regard to the attitude which is to be adopted in the elucidation of a child's illness. It is a truism that the history, which is so valuable in the case of adults, is apt to be faulty and inaccurate in the case of children. It is also usually held that a child is a bad witness and unable to locate its abdominal troubles, but personally I prefer to regard the child as an adult in miniature and oftentimes with gentle encouragement he

or she can tell you what you want. Infants almost always, and many other one off by their crying at the sight of a doctor, only hope lies in the exercise of patience. Perhaps Luke Fildes's doctor was right after all. Inspection is calculated to give most valuable information, but it must be with the clothes off.

DIAGNOSIS

I am not going to consider abdominal injuries, and there are certain organs which can be dismissed from our minds because they so rarely figure. The stomach and duodenum interest us only from the possibility of pyloric stenosis or duodenal atresia. The liver and the bile passages need hardly be considered, and the pancreas is also ruled out by the rareness of its disease in the young. However, during the last few weeks acute cholecystitis has been operated on in a child of 3 at St. Bartholomew's Hospital.

The spleen and the female genitalia can almost be disregarded, although I have elsewhere² published a drawing from life of torsion of the broad ligament and Fallopian tube in a girl aged 11 (Cassidy and Norbury's case, *Lancet*, 1911). External hernia which has become strangulated is not likely to be overlooked if one always insists on seeing the whole child stripped. We are left, then, with varying pathological states of the peritoneum itself and the intestinal tract. The problem sounds a simple one.

The first premiss is abdominal pain, presumably acute, and of recent or sudden onset. The difficulty is the localization of the pain. I think it may be accepted that visceral pain is a referred pain, not felt in the organ itself, but in the area of distribution of those spinal nerves whose nuclei lie closest to the spinal nuclei of the afferent sympathetic nerves from the seat of disease. In the early stages abdominal pain is either diffuse or central in position and it requires an intelligent child patient to tell you where the pain is felt. If the child is old enough it is well worth asking, but not too much reliance must be placed on the reply. It may be judged by the child's behaviour whether the pain is constant or intermittent. In the latter case crying and screaming will result with quiet periods between. If the pain is constant the child is fretful and sleepless and resents all interference. The pain of obstruction is well known to be colicky in nature, and no better example can be seen than in intussusception where the onset is usually with screaming and a doubling up of the legs on the abdomen. This precedes vomiting. Other varieties of obstruction manifest this intermittent pain and the best information will be secured if the abdomen is watched and palpated when the attack is in progress. The pain due to enlarged ileo-caecal glands is also intermittent, probably from interference with regular peristaltic waves in the neighbourhood of the ileo-caecal valve.

Continuous pain is more evident in peritoneal inflammation, and the characteristic attitude—the dorsal position with the legs drawn up—is an effort on the part of the patient to secure relaxation of muscles. Movement is resented. If there is evidence as to the place where the pain is most acute, there will probably be rigidity in the same area and the causative lesion of the peritonitis may be definable. Though appendicitis in its early stages causes diffuse or central pain, sooner or later it nearly always settles in the right iliac fossa and unless there are physical signs here or hereabouts I defy the clinician to make the diagnosis with certainty. Allowance must of course be made for variability due to a high appendix, a retro-caecal appendix, or a low or pelvic one.

Vomiting may next occupy our attention. That of pyloric stenosis is so characteristic as almost to justify a diagnosis without examination. When a small infant ejects stomach contents, without bile right over the edge of the bed—the record, I believe, is seven feet—it is very suggestive. If in the same child there is a history dating from shortly after birth with visible gastric peristalsis, pyloric stenosis is almost certain. If careful palpation of the right hypochondrium reveals a small tumour, best felt by the pressure of one finger it becomes clear that the case is one of hypertrophic stenosis of the pylorus. Such children do not cry, but they writho as the peristaltic

If there may be able to

Obstruction differs from that of peritonitis, and in the early stages of the disease it often comes on shortly after taking food. It is not usual nor to talk about the progressive changes of the vomit from gastric to bilious, from bilious to stercoraceous and even faecal, because we are supposed to arrive at a diagnosis before these changes occur. Certainly it is true that stercoraceous vomiting in a child means a hopeless prognosis, but sometimes it has already occurred before the doctor is consulted. The vomiting of peritonitis and inflammatory abdominal lesions is associated with some degree of collapse. It is less forcible than that of obstruction, but nausea and retching are pronounced and quite often the vomit is bilious from the start. In the late stages of peritonitis the act of vomiting is almost effortless, and the vomited fluid is dark in colour, partly from altered blood, and offensive in odour. This is the product of the stage when paralysis of the intestine has set in, the stomach remains active almost to the end.

Abdominal pain and vomiting alone do not make a clinical picture unless we know the precise seat of the pain. If it is in the right iliac fossa the chances are strongly in favour of appendicitis, but ileo-caecal adenitis may also be responsible.

The state of the bowels is the next symptom of importance, and thus may entirely dominate the diagnosis. What comes out of a man is the lawful criterion of the state within. If a child with abdominal pain and vomiting is also passing blood per anum the odds undoubtedly favour intussusception. Piles and polypi also cause bleeding by the rectum, but there are few lesions which cause the evacuation of mixed blood and mucus resembling prune juice which is so characteristic of intussusception. If this is not mixed with faecal matter a rectal examination, which is, of course, a part of the routine abdominal examination, will go far to settle the diagnosis. Severe diarrhoea and dysentery are associated with bloody stools containing mucus, but some faecal matter is usually present. During the diarrhoeal and vomiting season in hot summers at children's hospitals cases of intussusception may be overlooked, but it is consoling to know that intussusception is not increased in frequency by such epidemics, and if an intussusception baby does turn up among the other patients it will almost certainly be the best-looking child, and most likely a boy. 70 per cent of the intussusception babies under 12 months of age are males, and nearly all of them are well nourished. The contrast in appearance with the miserable "D and V" infant is most striking. Blood may be passed in the stools in very toxic cases of peritonitis, but the blood is usually dark in colour, and it probably comes from the small intestine.

Pus passed by the rectum is a striking symptom, and a pelvic appendix abscess not infrequently evacuates itself in this way. Pus per anum, however, does not necessarily mean an intraperitoneal infection, and search must be made for the abscess, which may be connected with bone disease.

Now as to the question of diarrhoea or constipation. The latter is the commoner in acute abdominal disease because the bowel is either obstructed or the peritoneum is inflamed and both these conditions will account for peristaltic arrest. It is important to remember, however, that diarrhoea is quite common at the onset of acute appendicitis, and that it occurs also in tuberculous peritonitis, though in this disease there is often a history of alternating diarrhoea and constipation. The three symptoms, sudden abdominal pain, vomiting, and constipation at once make one think that the condition present comes under the heading of "the acute abdomen" and we may well pass on to a consideration of the physical signs whereby the differential diagnosis is made.

Physical Signs

To return to "The Doctor" first watch your child, then diagnose him. Much may be gained by sitting by the bedside observing the position and facial aspect of the

child. Note whether he cries or lies still. Most children in health are either very much awake or very deeply asleep. In apathetic or listless child is clearly ill. If by any chance there is the sweetish odour of acetone noticeable the explanation may be simple, but remember that retention of some degree is consequent on repeated vomiting from whatever cause. It may be an effect, and we are not to ascertain the cause.

The position of the patient has already been referred to, and the dorsal decubitus is preferred by nearly all children with peritoneal lesions. Occasionally, however, an appendix patient will prefer to be on the right side, and flexion of right hip and knee will be found. Restlessness is another characteristic of severe peritoneal involvement.

Pulse and temperature I shall not consider separately because they are very poor guides to the diagnosis unless the case is watched, and usually it is incumbent upon us to arrive at a diagnosis at the first examination, or very soon after. A pulse rate of 120 in a child may result from a very trivial cause. Similarly the temperature of a child may shoot up with very little to account for it. An infective lesion is rarely afebrile throughout the course of the illness and this certainly applies to appendicitis, but the onset is often associated with some collapse and the temperature may be subnormal. Intestinal obstruction does not as a rule cause fever unless the stage of secondary peritonitis be present. Rigors sometimes occur at the onset of peritonitis, and in young children they may be represented by fits. Repeated rigors with a high peaked temperature chart are suggestive of portal pyaemia. Inspection of the abdomen may reveal definite retraction of the anterior abdominal wall. As already mentioned, this is common in meningitis and after severe diarrhoea and vomiting. In simple intestinal colic also it is met with intermittently.

The most common state of the abdomen in disease is distension, and this applies equally to obstruction, unless it be very high up, and to peritonitis. It is a characteristic feature of tuberculous peritonitis. If there are also several masses to be felt in the abdomen with evidence of free fluid these signs go far to make this diagnosis clear, especially if there be a history of alternating diarrhoea and constipation. Intestinal obstruction naturally leads to abdominal distension, and if this be coupled with visible peristalsis the problem becomes a question of the cause and site of the obstruction. It is not usual, however, to find much distension, or visible peristalsis, in cases of intussusception in the early stages.

Inflammatory masses or tumours of the abdomen may cause both visible and local protuberance. This is not often seen in the right iliac fossa in connexion with disease of the appendix, if there be such a visible tumour in appendicitis it nearly always means that there is an abscess. It is important to remember that the commonest tumour in the hypogastrium is a distended bladder, and until it is quite certain that the child has passed water it is dangerous to attempt a diagnosis of any tumour in the lower abdomen. If any doubt arises a catheter should be passed.

Visible peristalsis has already been referred to, and is a most valuable diagnostic sign of organic obstruction, whether it be of the stomach or small or large intestine. Such peristalsis can often be excited in the case of the stomach by a drink, or by stroking or flicking the abdomen, and when it is seen it is commonly painful for the patient. It should be remembered that such obstruction may be due to lymph exudate, the result of peritonitis binding coils of small intestine together. Its presence, therefore, does not eliminate peritonitis from the diagnosis.

Respiration in children is normally of the abdominal type. If there is limitation of the normal respiratory excursion it suggests that the quiescence is due to inflammation of the peritoneum. Most children can be persuaded to take a big breath, particularly if the examiner shows them how it is done by opening his own mouth wide and inspiring deeply. If then respiratory movement is absent over the whole abdomen it is indicative of general peritonitis. If it is absent over part it will usually be the lower portion. Such limitation is common in appendicitis with local peritonitis, and in pelvic inflammation.

Palpation

If an abdominal surgeon is really a physician who can work with his hands there is no doubt that constant practice will almost endow him with eyes at the tips of his fingers. The hand, warm, reasonably soft, and gently applied, is the surest instrument in the diagnosis of abdominal disease. Constant inspection of the interior of the abdomen enables the surgeon to visualize the state of its contents. The ideal to aim at is to see before operating what is the other side of the abdominal wall. The method of palpation must be adapted to the patient. There must be no hurry, and there should be little guess-work. Every consideration of history, symptoms, and visible signs leads up to the final test of abdominal palpation. For this purpose the patient should be flat on the bed. The abdomen cannot be palpated with the patient in the Fowler position. The hand also should lie flat on the abdomen, and when the child ceases to resent this, gentle deep pressure should be exerted by flexion at the metacarpophalangeal joints. Unless the child can be coaxed sufficiently to lie still without crying this examination will be a failure, and it may be necessary to give an anaesthetic to get rid of voluntary contraction of the abdominal muscles. Much may be learnt by keeping the hand flat upon the abdomen, if the child is crying, and waiting for the relaxation which comes before the next inspiration, then the pressure can be increased, and thus, if otherwise unpalpable tumour may be felt. This method succeeds admirably in cases of intussusception and pyloric stenosis where the discovery of a tumour is essential to the true diagnosis. In both cases an anaesthetic is justifiable if satisfactory palpation cannot otherwise be secured. Sensitive parts of the abdomen should be palpated last, negative observations are just as valuable as positive ones.

Two hands may be required for successful palpation, and this is the only way to decide the nature of any lumbar swelling. Bimanual examination, with one finger in the rectum and the other hand flat on the abdomen, is of the greatest use in children, but this should be the last step in examination. Where intussusception is suspected this method should always be used. The apex of a large intussusception can be felt by the rectal finger, and a complete confirmation of the diagnosis may be obtained by finding an absence of the normal resistance in the right iliac fossa. Between 60 and 70 per cent of intussusceptions are of the entero-colic type and begin near the ileocecal valve, therefore if the tumour reaches the rectum it is clear that a gap must be left in the right iliac fossa. This "signe de Dance," as it is called, provides very positive evidence. A pelvic abscess, or intrapelvic tenderness, may be impossible of diagnosis except by careful rectal examination. The presence of any vaginal or rectal discharge should be looked for when this pelvic examination is made.

There are two types of hyperalgesia which can be elicited by palpation—superficial and deep. Cutaneous hyperalgesia or hyperaesthesia is best discovered by pinching up the skin, but personally I have not much faith in the accuracy of this method of diagnosis. Deep tenderness, or pain caused by firm pressure through the abdominal wall, is, of course, very suggestive of an inflammatory lesion beneath the examining hand.

Muscular rigidity is one of the most important signs to be found on palpation. It varies greatly in degree, and is well known to occur in its severest form in perforative peritonitis. In the case of perforated gastric ulcer the diagnosis may almost be made on a degree of muscular tension, which is appropriately called "board-like" rigidity, but this is not a lesion we are likely to encounter in children. I know of a case in a child of 12, and I believe it has been described several times in children under 5, but I do not suppose it was diagnosed.

Rigidity of the abdominal wall is essentially an involuntary reflex response, and usually to a subjacent peritonitis. In children, however, I have seen general peritonitis with quite a soft belly wall, and its degree of contraction depends to some extent on the normal muscularity of

PERCUSSION

the patient. Simple colic may be relieved by pressure rather than by but pressure rather relieves than obstruction, before peritonitis ensues, rigidity is absent. If oedema of the abdominal wall be found, a clear indication of a subjacent suppuration.

Abdominal Tumours

Some abdominal tumours may be seen as well as felt. It is important to remember the common physiological tumour of the child—namely, a full bladder. Tumours of an inflammatory nature may be felt in any part of the abdomen. They are usually tender, and, if near the surface, they will almost certainly be dull on percussion. It must be remembered, however, that there are such things as gas-containing abscesses, and as a matter of fact I have found them more often in children than in adults. Whilst yielding some resonance on percussion, they are definite masses and exquisitely tender.

One of the abdominal masses which is a source of error in diagnosis is a tongue-like process of the right lobe of the liver. This is Riedel's lobe, and I have known it mistaken for the tumour of an intussusception. Similarly the kidney, usually the right one, may be mistaken for a pathological tumour apart from renal disease. If the spleen is palpable it is almost certain that it is diseased.

The retinal diagnosis of an abdominal tumour which is not inflammatory depends on its position. Multiple masses are felt in tuberculous peritonitis, and these are usually omental in origin, being fibro-calcareous deposits with or without suppuration. These, again, may be mistaken for intussusception. The other common cause of multiple lumps in the abdomen is constipation, which masses of solid faeces may be arrested along the course of the colon. These have a characteristic doughy feel, and are definitely limited in position by that of the colon. Sometimes an enema is needed to differentiate them from omental masses.

Percussion

All abdominal percussion should be light. Tenderness under such examination is very suggestive of peritonitis. Dull areas should be carefully mapped out, and the flanks especially must be percussed. Shifting dullness in the flanks is the surest evidence of free fluid, unless there is enough fluid to give an obvious thrill. Where peritonitis is diagnosed dullness in both flanks means that it is general peritonitis. In appendicitis there is often dullness in the right flank only, and this is commonly associated with rigidity of the oblique muscles. When the small intestine is overloaded with fluid and gas splashing may be elicited.

Auscultation

Not sufficient use is made of the stethoscope in abdominal diagnosis. Peristalsis of unusual activity is audible without a stethoscope. Normal peristalsis can be heard with one. Entire absence of peristaltic sounds is very strong evidence of peritonitis, local or general.

CONCLUSION

In concluding my remarks I must, if I wish to make this review of abdominal crises in any way complete, forsook the purely clinical method, and for purposes of description assume the diagnosis before describing the signs of disease. I have already said that examination of the urine may point the way to the correct conclusion, and this applies, above all, to that variety of infection which is due to the *Bacillus coli*. I am confining myself to that manifestation of the disease which has an acute onset and essentially abdominal symptoms. It is quite common in children, and affects girls more often than boys. Diffuse abdominal pain, nausea, vomiting, and constipation are all present. Shivering may occur at the onset, and the temperature is high. There is a rapid pulse and headache may be complained of. The tongue is thickly coated and dry, and the face tends to be flushed. The abdomen is tumid and tender, and often this tenderness is most marked in the flanks, which may be rather rigid. It is this situation of the tenderness and rigidity which frequently puts one on the track of the right diagnosis. One or other

In 4 cases gall stones shadows by the surrounding shadows. In the other 3 the hazy shadow indicated cholecystitis. In the operation, whilst the gall bladder contracted, the sort of green pathological change in the wall was the sort of green pathological change. Cholecystectomy was performed.

GROUP IV—GOOD GALL-BLADDER SHA- At Operation Functioning Gall Bladder

In this group there were 3 cases. In one case the gall bladder contained several calculi, but the wall was not thickened and it contained clear bile (see Fig 4). In this case an ideal cholecystectomy was performed. In the other two cases the gall-bladder wall, although not functionless, showed naked-eye evidence of pathological change and cholecystectomy was performed.

GROUP V—CASES OF OBSTRUCTIVE JAUNDICE

The method was employed in 8 cases of obstructive jaundice. Contrary to the experience of Carman, we found no serious untoward effects. In 4 cases there was no reaction, in 4 slight nausea, and in 2 transient vomiting. In no case was any shadow visible in gall bladder or ducts. In 6 of these cases a stone in the common duct was the causative factor, and in 4 of these the gall bladder was shrunken and functionless. In one of the four the whole biliary duct system was distended with "white bile." In two a previous cholecystectomy had been performed. In one case of carcinoma of the head of the pancreas the biliary passages were filled with thick creamy bile which had effectually prevented further biliary excretion. In the last case a carcinoma of the hepatic ducts (already referred to) completely blocked the passage. The lesson to be learned from this group is that in jaundiced patients the method gives little, if any, help in localizing the lesion.

GROUP VI—DEFORMED GALL-BLADDER SHADOW At Operation Local Cholecystitis

In one case an hour glass-like shadow in the radiogram was found at operation to be due to a localized hard inflammatory mass in the wall of the gall bladder, the remainder of which appeared healthy (see Fig 6). A cholecystectomy was performed, and on sitting up the organ a dense fibrous mass, three quarters of an inch in diameter, was found in an otherwise healthy wall.

COMMENTARY

Our experience in this series of cases leads us to believe that in cholecystography we now possess a valuable aid in the diagnosis of gall-bladder disease. When a gall bladder shadow is visible, if it be of normal density and contour, gross disease may be excluded but mild cholecystitis may be present. Gall stones existing no shadow in the ordinary radiogram may be shown up as negative shadows. Care must, however, be exercised not to mistake gas in the overlying colon for a gall stone. Given correct technique the absence of a gall bladder shadow indicates one of three conditions:

- (1) Obstruction of the cystic duct by a stone within it or in Hartmann's pouch, or by fibrosis, catarrh, or neoplasm.
- (2) A gall bladder so filled by stones that dye-laden bile cannot enter.
- (3) A gall bladder so diseased or shrunken as to be functionless.

In cases where a preliminary radiogram has shown doubtful shadows suggestive of gall stones, the accurate localization of the gall bladder gives confirmatory evidence, the method being thus comparable to pyelography in cases of renal calculus. In such a case, under the care of Mr Henry Wade, the preliminary x-ray photograph showed what appeared to be a renal calculus as well as gall stones. The sites of the calculi were accurately defined by pyelography

and cholecystography, and both conditions successfully dealt with at one operation. When a palpable lump is present in the right hypochondriac region it is possible by cholecystography to determine whether it is a new growth in the liver or a distended gall bladder. In a case which was lately under our care the patient had recently been operated on for an endothelioma of the thigh. He developed a painless, rounded, and mobile swelling under the right costal margin associated with an intermittent rise of temperature. A cholecystogram showed that the gall bladder was functioning normally and was situated below the margin of the swelling, thus confirming the diagnosis of secondary growth in the liver.

In order to simplify the test the dye may be given by the mouth, either in capsules or in pill form. Carman has practised this method of administration extensively in the Mayo Clinic and recommends it for general use. We have used the oral method in but a few cases. The results were so inferior to those obtained by the intravenous administration of the dye and the latter so much more accurate and certain that we now practise it exclusively.

The outstanding feature of cholecystography is that it is a means, not only of demonstrating anatomico-pathological changes in the gall bladder, but also of testing the functional capacity of the organ. Whilst modifications and improvements of the method will doubtless follow further experience, we believe that it will have a permanent place as a method of physical diagnosis.

In conclusion we desire to express our thanks to Mr Henry Wade for permission to include three cases which were under his care in this series, and to Mr Leslie Stewart for his help in the investigation of these cases.

EMBRYOMA OF THE TESTIS

SUDDEN DEATH FROM THROMBOSIS OF PULMONARY VEINS (With Special Plate)

BY

A. E. WEBB JOHNSON, C.B.E., D.S.O., M.B.,
F.R.C.S. (ACCS),
SURGEON TO THE MIDDLESEX HOSPITAL.

It is not at all uncommon for a patient with a tumour of the testis to seek advice in the first instance on account of secondary deposits, either in the loin or even in the posterior triangle of the neck when metastases have travelled along the thoracic duct, but the extreme case of death occurring without any tumour having been noticed must be almost unique.

An officer, aged 31, was admitted to No. 14 General Hospital, Boulogne Base, on November 15th, 1915, as a walking case, having been sent down from the front with a diagnosis of "lumbago." He was admitted in the late evening, and went to bed. He complained of pain in the right lumbar region which he said was proving distinctly trying under the conditions of life in the front line trenches. Under other conditions he did not think the pain would have worried him. He stated that he only had it on movement and that he was quite comfortable when in bed. He first noticed it at the end of September. He remained on duty until November 5th for two or three days after reporting sick. He had a slight rise of temperature.

The morning after admission to the base hospital he was up and about, attending to his toilet and visiting some of his friends who were in neighbouring rooms. As he was talking to a brother officer he suddenly fell down and appeared to be in a dying condition. The medical officer saw him immediately and within a few moments there were several of us in attendance. In spite of every effort to resuscitate the patient it was soon obvious that he would be dead in a few minutes. His appearance was that of a man receiving no oxygen into his circulation although there was some shallow respiration. The pulse rapidly failed, and within about ten minutes of the appearance of symptoms he was dead. A post mortem examination was made and since his symptoms were suggestive of pulmonary thrombosis or embolism the thorax was examined first. The lungs and heart were removed together along with the contents of the posterior mediastinum. The pulmonary veins were opened and some anti mortem thrombus was found in them. A small soft almost gelatinous mass about

FIG 1—Normal gall bladder shadow thirteen and a half hours after injection. Duodenal tube seen not to have passed pylorus. At operation healthy gall bladder and ducts.

FIG 2—Normal gall bladder shadow fourteen and a half hours after injection. At operation healthy gall bladder and bile ducts.

FIG 3—Normal gall bladder shadow (encircled by coils of duodenal tube). Fifteen hours after injection of dye.

FIG 4—Gall bladder containing numerous stones. The gall bladder shadow is dense indicating little impairment of its concentrating function. At operation the gall bladder though containing stones showed little pathological change and was not removed.

FIG 5—Gall bladder seen overlying tip of last rib and containing several large stones. The shadow is faint indicating impaired concentrating power. At operation gall bladder thickened and fibrotic containing stones.

FIG 6—Gall bladder angular with slight hourglass contraction. At operation localized infiltration of wall.

BLOOD TRANSFUSION IN CARBON MONOXIDE POISONING

No 53 Casualty Clearing Station, suffering from the effects of a 59 German high-explosive shell, which set fire to their dug-out

the size of a chestnut, was found in the posterior mediastinum, with the thoracic duct running through it (Fig 1). Exploration of the abdomen revealed the presence of a mass the size of a clenched fist in the right lumbar region, with the inferior vena cava running through it (Fig 2). The kidney was healthy, and the mass in the lumbar region did not involve the adrenal body, so it was thought that it must be due to glands secondary to a primary growth elsewhere. Palpation of the testis revealed no gross abnormality, but there was a small prominence about the size of a pea on the lower part of the body of the testis near the globus minor of the epididymis. The prominence was removed, and on cutting it across, the small tumour, of the testis was seen.

Testis was removed, and on cutting it across, the small tumour, of the testis was seen. The specimen was sent to the Bland Sutton Institute of Pathology at the Middlesex Hospital where they were examined by Professor Browning. He found that the primary tumour in the testis was a small embryoma with the usual characteristics of these tumours. Its microscopic appearances are well shown in Figs 4 and 5.

The pathology of these tumours has been investigated by Nicholson, and his paper in the *Guy's Hospital Reports*, vii, 1907 (p 249), should be read by all interested in the subject. The origin of embryomata of the testis is not absolutely definitely determined, but Nicholson says "There can be no doubt that these tumours, which contain derivatives of the three blastodermic layers, must have originated in a cell which is still capable of producing the three primary layers of the embryo."

These tumours are benign at first, but a malignant stage may supervene in any or all of the component layers. The result may be a mixed tumour, a hypoblastic tumour like a columnar-celled carcinoma, a mesoblastic tumour such as a "dermoid," or a growth resembling a chorion epithelioma. And, as Nicholson says, "not only may one layer be greatly in excess of the others, but one tissue may assume this supremacy."

In the present case the lumbar glands were metastatic deposits from the tumour in the testis. The small mass in the posterior mediastinum was of a similar nature microscopically and was evidently a metastasis which had been arrested on its way along the thoracic duct and had grown in that situation.

The case presents many points of interest. In the first place, it must be extremely rare for a malignant growth of the testis to lead to death without either primary or secondary tumours having been suspected. Certain lessons are emphasized by the post-mortem findings. It is clearly shown that the size of a primary tumour is no indication of the extent of malignant disease. It is also dramatically demonstrated that the examination of the contents of the scrotum should always include an examination of the contents of the scrotum. We are accustomed to insisting on this in clinical teaching, but it is not often that the lesson is driven home so tragically in the post-mortem room.

VENESECTION AND BLOOD TRANSFUSION IN CARBON MONOXIDE POISONING

BY
SM C GORDON-WATSON, KBE, CMG, FRCS,
SURGEON TO ST BARTHOLOMEW'S HOSPITAL

The recent tragedy in which a medical man lost his life after undue exposure to motor exhaust fumes in his garage calls attention to the value of blood transfusion in carbon monoxide poisoning.

In the *British Medical Journal* of April 25th (p 812) Dr James Holmes (Bury) writes suggesting venesection and transfusion as a possible method of treatment in these cases, which he states has not, so far as he knows, been tried. The great value of venesection and blood transfusion in carbon monoxide poisoning was brought forcibly to my notice in 1917 when I was consulting surgeon to the Second Army in France.

The following account of six cases of carbon monoxide poisoning, two of which were treated by venesection and blood transfusion, at which I assisted, is, I think, worthy of record. The men were admitted on June 20th, 1917, to

The notes of the cases were taken at the time by the medical officer in charge. Unfortunately I am unable to give him the credit which is his due, as his name has escaped me and is not attached to the notes which he very kindly made for me at a time when all the medical officers were overworked in dealing with the casualties after the battle of Messines. It seems possible that some other gas or gases besides carbon monoxide may have been responsible for the remarkable ashen hue displayed by these men. The cases, however, were regarded as carbon monoxide poisoning by the mining medical expert to the army. I feel certain that the two cases treated by venesection and transfusion would otherwise have succumbed.

Ten men were in an old German dug-out when the side was blown in by a shell. The dug-out was set on fire, due to shavings on the floor, and bedding filled with shavings strewn about. A heap of Mills's bombs, at least twelve in number, was lying near the window where the shell struck and these also exploded, together with much small arm ammunition as the fire increased. Six of the men were brought to the casualty clearing station, none of the others escaping. Four of the men were almost black as to lips and ears, with a dirty earthy colour of the skin, two were a deep dusky red. There was no marked obvious respiratory distress, except that in some of them respirations were increased. There were no bronchial symptoms, no cough, no expectoration.

It does not seem to be realized generally that the explosion of ammonal (the explosive of Mills's bombs) in a confined space, owing to deficient oxidation, gives rise to a large evolution of carbon monoxide gas. The explosion of the cordite of the small arm ammunition does so also in a lesser degree.

The cases presented certain differences, each showing some special characteristic. Little effect was produced by oxygen. Even when administered pure, without air, for prolonged periods the dark colour was not in the least changed. Artificial respiration combined with the administration of oxygen was not tried. Two of the worst cases were trans fused, with marked benefit, and they probably owe their lives to this measure being carried out.

The blood had the same characters in all—thick, black, tanny, flowing from the veins with difficulty and clotting at once. In the first case the coagulation did not take place for some time. The blood clotted solidly, and when left a dark chocolate-coloured fluid formed from which a clear straw-coloured serum separated. The blood was examined by the pathologist, who was unable to detect any definite change spectroscopically, he did not think haemolysis had taken place. Smears of blood examined showed nothing definitely abnormal.

The urine passed by all the patients was exactly the same in colour—a dark straw colour with a bilious tinge, though in all for these constituents were not detected on examination. Albumin was not present, and no sugar in any case, the urine being examined to light. None of the patients showed any nerve manifestations, the reflexes were normal, and no paralytic symptoms were observed.

All the men extricated themselves from the fire, the severe symptoms coming on later. The one case least affected states that he was dizzy and unable to stand after getting out of the dug-out and had to lie down. He vomited severely on his way to the ambulance and he was the only man of the series who vomited.

The account given deals with the cases up to the fourth day.

An effort was made to ascertain the percentage of haemoglobin, but the blood was so thick that it would not spread evenly and the light could not be seen through in the type of instrument available. Major Ellis, the pathologist, was unable to give the haemoglobin percentage, although he made various trials.

Two surprising almost startling features of the cases were (1) that these men developed so dark a colour—almost black in the mucous membranes—and yet had so little respiratory

distress, (2) that life was compatible with blood so thick (almost tanny) and black. The cherry-red colour frequently described was not a feature of any of the cases.

CASE I—Transfusion Case

Pte. H on admission had dark black lips and slaty grey skin. Pulse 100, respirations 18. Pupils widely dilated and not reacting to light. He was quite conscious and able to tell what had happened. He was so sensible and apparently improving that bleeding was not considered necessary. Oxygen was administered continuously. He vomited slightly shortly after admission.

June 21st. Next morning he was much worse, not quite conscious, resented interference, complained of headache, very blue as to ears, lips, and nose. Pulse 112 respirations 22. A pint of blood was extracted when the patient began to sigh and bleeding was stopped. His condition improved, but he remained only semi-conscious. Oxygen was then given pure by inhaler. At 2.15 p.m. he was still a very dark colour and was again bled, during bleeding the pulse at first improved, but later became quicker and weaker, so bleeding was stopped after 15 oz. had been extracted. The blood was very dark in colour, thick and tanny, and clotted at once. Pure oxygen was then administered through a nitrous oxide inhaler, but this did not affect his colour in any way. Pulse 130, respirations 20. He was then transfused by Colonel Gordon Watson and Major Robertson with blood by the Record syringe method, 1,000 c.c.m. of blood being given. After transfusion the pulse was 126, respirations 28. He then had a rigor lasting fifteen minutes, the pulse became full and bounding, and he perspired freely. He had become more cyanotic, but a red tinge was noticeable in the mucous membranes which was absent before. He was able to speak when roused. Morphine, 1/4 grain, was given as he was a little restless.

June 22nd. The patient had a good night, was much improved, quite conscious, but quiet. Still blue as to lips and ears. Complained of brow headache. Pulse 80 respirations 18. During the night the respirations were reduced to 14. There was incontinence of urine all night, but he stated he had always had some difficulty.

June 23rd. Much improved but very quiet and depressed. Speaks when spoken to and is able to remember what happened. Very sleepy, but clear mentally. (This man was the last to leave the burning dug out.)

June 24th. Jaundiced but not deeply, otherwise improved. Mental condition quite clear and cheerful.

He continued to improve, the jaundice becoming less, and he was evacuated on June 30th.

CASE II—Transfusion Case

Cpl. B. On admission his lips and ears were pale grey in colour, almost bloodless, with a slaty grey skin. He was only partially conscious, was restless, and delirious from time to time. Pulse 138 and full respirations 40, but very shallow. The pupils were widely dilated and did not react to light. Oxygen was administered. He quickly became worse fighting for breath, the oxygen being thrust away every time, and crying out, "I want to breathe." A pint of blood was then removed, and the change was most marked, the restlessness ceased, and he became quiet and slept. As the restlessness returned a little, 1/4 grain of morphine was given.

June 21st. Still a very bad colour and inclined to be restless. Respirations 25 pulse 104. The pupils were not dilated and reacted to light. Colour still a pale grey almost waxy and deathlike. He was unable to pass water and a catheter was passed. Owing to want of improvement he was first bled, about three quarters of a pint being removed, and then transfused 1,000 c.c.m. of blood being given and about 500 c.c.m. of normal saline by the Record syringe method. During the transfusion he was very restless, thirsty and vomited once. Pulse 80. On returning to bed he had a rigor lasting twenty minutes. Pulse 120 and very full respirations 18. He again became very restless and morphine was given twice during the night. There was no immediate change in colour noticed.

June 22nd. Had rather a restless night. Pulse 24 respirations 18. Has passed urine naturally. Colour of lips very much improved, a pink tinge on lips and ears being noticeable. No restlessness. Says he feels well but mentally is quite abnormal, wandering in speech, repeating himself over and over again and sometimes returning stupid answers. Temperature last night 100° this morning 98°.

June 23rd. Improvement most marked. Lips and ears a pale pink skin still grey more rational but still somewhat lazy, can tell and answer questions does not remember being transfused. Pulse 60, respirations 16. Able to take his food.

CASE III

Pte. M. was almost unconscious on admission becoming unconscious later, restless delirious, throwing himself about dark black lips and ears and dark fingers skin almost slate colour. Pulse 126 respirations 40. The pupils were widely dilated and did not react to light. Oxygen was continuously administered, but

seemed to have no effect on the colour nor on the breathing. Shortly after admission one pint of blood was removed, after which he at once became quiet and slept. This man on admission was by far the worst of the six cases, but recovered more quickly than the others. During the first night the pulse rate was 138, gradually settling down to 100.

June 21st. Next morning he was much improved, but the lips were still decidedly dark and the skin grey. He was very quiet speaking only when roused. Pulse 100 respirations 22. Felt weak and had a frontal headache. Pupils normal and reacted to light. The mental condition improved during day.

June 22nd. Had a good night and was much improved. Colour better, and definite red tinge observable in mucous membranes, ears a dark red. Pulse 60 respirations 15.

June 23rd. Much improved mentally—began to observe more, the lips were still a dusky red. Was very quiet.

Subsequently he improved daily and was evacuated on June 30th.

CASE IV

Lieut. Cpl. G. was on admission a very dark red as to lips, ears and finger tips, with a grey skin. He was breathing easily, the pupils were widely dilated, not reacting to light and accommodation, he was quite conscious and able to talk, but was very quiet. Pulse 90 respirations 18.

June 21st. Pulse 85 respirations 18. Lips still more than a dusky red, the pupils were normal and reacted to light. He slept well but had severe headache and feeling of tiredness and weakness apparently very sleepy.

June 22nd. Still a dusky red somewhat depressed no headache only speaks when spoken to.

June 23rd. Had not yet resumed a natural colour. He was brighter but very quiet, quite clear headed and able to describe clearly all that had happened previously. Oxygen was administered at intervals to this man during the first day and night.

His condition improved rapidly, and he was evacuated on June 30th.

CASE V

Pte. C. was very quiet and depressed on admission, but was able to talk when roused. His lips were dark blue and no tinge of red was visible. The skin was ashen grey in colour. Shortly after admission he became restless and later lapsed into unconsciousness with marked twitching of the right arm and leg, and right side of face. Although unconscious he resented interference. Pulse 150 respirations 40. Morphine 1/4 grain was given for restlessness. He was then bled, which he slightly resented, about a pint being removed. The breathing became easier, muscular twitchings altogether ceased and did not return, but he still remained unconscious. Oxygen was continuously administered throughout the evening and at intervals during the night.

June 21st. Next morning he was much improved—conscious but heavy mentally. He complained of headache. Was still very grey, and lips a dark blue. Pulse 120 respirations 25 temperature 100°. Later in the day his colour gradually improved. Pulse 120 temperature 100.8°.

June 22nd. Great improvement mentally, and colour better but still dusky. Pulse 90 respirations 18 temperature 98°. No headache heavy mentally but conscious and able to talk.

June 23rd. Mucous membranes still dusky tongue pale and furred very heavy and inclined to sleep all day. He was unable to pass his water early in the day, and as he was in distress it was drawn off. Later in the day he passed water naturally. His general condition was very much better.

He made a rapid recovery, and was evacuated on June 30th.

CASE VI

Pte. W. was the least affected. He was a dusky red on admission and his pupils were widely dilated and did not react to light. His breathing was quite easy. Pulse 70. He had vomited severely in the ambulance coming down. On the following morning he complained of a severe headache and was still dusky, remaining very quiet all day.

June 22nd. Almost normal except for dark red colour of lips and ears very sleepy no headache.

June 23rd. The mucous membranes were still a dark red tongue pale, otherwise normal. He was bright and took an interest in the patients in the ward. This man received no special treatment. He was in the burning dug out about four minutes and was the last but one to get out. However he was not near the window where the bombs were exploding.

June 24th. Improvement maintained. Colour more nearly approaching normal but still somewhat dusky. Intelligence clearer. Had a copious crop of herpes labialis. A peculiar coincidence was the appearance of a similar crop in the donor of the blood transfused.

June 25th. Slightly jaundiced, otherwise improving in all respects.

His condition continued to improve and became nearly normal. He was evacuated on June 30th.

British Medical Association

PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, BATH, 1925

SECTION OF MEDICINE

The Right Hon Lord Dawson of PENNYCOCK, KCMG, CB, MD, FRCP, President

DISCUSSION ON
THE USES AND ABUSES OF ENDOCRINE
THERAPY

OPENING PAPERS

I—W LANGDON BROWN, M D Cantab, FRCP,
Physician St Bartholomew's Hospital

I SHALL deal mainly with the uses of endocrine therapy, feeling sure that Professor Sale Vincent will deal faithfully with the abuses.

I would define the basis of a rational endocrine therapy as follows. Certain glands are known, others are assumed, to pour into the blood stream secretions which produce pharmacodynamical effects on other tissues of the body. As Starling pointed out twenty years ago, whenever we give a drug we imply thereby a belief that the functions of the body can be influenced by chemical means, and nothing would appear more reasonable than to use intelligently in disease those very drugs by which the body is enabled to do its own work in health. We may use an endocrine preparation such as thyroid extract or insulin to replace a deficient internal secretion, or we may use it simply for its pharmacological action, such as adrenaline, for one or other of its stimulant effects on the sympathetic nervous system. But it must be observed that before endocrine therapy can claim a rational basis it must be shown that—

- (1) The gland in question forms an internal secretion.
- (2) The active principle or principles of this secretion can be extracted.
- (3) A method of administration of this extract can be found which will admit of its utilization by the body.

Now it must be admitted that the instances in which these criteria are all satisfied are few. So few, indeed, that clinicians confronted with urgent problems, have, not unnaturally, had recourse to more empirical methods. No objection can be made to this, empiricism has often won therapeutic success which had to wait long for scientific explanation (such as quinine for malaria and mercury for syphilis), and which in some cases has not yet received it (such as salicylates for rheumatism and colchicum for gout). The empirical method has always been suspect by the laboratory, although it is a procedure by trial and error just as the experimental method is, I think I may add, unfairly suspect, when one remembers that cod-liver oil was used for many years to the scorn of the experimentalist—until vitamins were discovered, and he scoffed no more. On this very subject of endocrine glands the pioneer observations were made at the bedside, Gull and Ord discovered the functions of the thyroid when the laboratory had made no more helpful suggestion than that it was merely to improve the contour of the neck, Addison was the first to point to the function of the adrenals, while the role of the pituitary was recognized clinically from the symptoms of the pituitary and Frohlich's syndrome. We have no need to apologize for using the empirical method, but we have need to employ it critically, realizing the fallacies to which its lack of controls exposes us. Of recent years two biochemical methods have been used to confirm the effects of an extract—the study of the basal metabolic rate and of the blood sugar curve. Of more limited application is the estimation of the calcium content of the blood. But I look forward to the formulation of other such tests which will prove valuable aids to our treatment and checks on our results.

I will now deal briefly with the evidence for the use of the principal extracts employed.

Thyroid Extract

Here all my three criteria are satisfied. The ease with which it is absorbed from the alimentary tract is probably due to the fact that the secretion of the gland entered this tract originally by the thyroglossal duct. Since no one disputes the efficacy of thyroid medication I shall content myself by saying that the active principle of the thyroid, which is presumably thyroxine, is a general quickener of metabolism—"the draught to the fire"—and is the sole secretion providing iodine to the body. Thanks to Leonard Williams, we know that the doses formerly prescribed were too large. A total daily dose of 6 grains of the extract of fresh gland seldom needs to be exceeded, and it is wise to start with not more than 1/2 grain three times a day. It is important to remember that the extract of the fresh gland is five times as strong as that of the fresh gland. It is worth while in children who fail to grow, who suffer persistently from nocturnal enuresis, who have night terrors, or who suffer from relaxation of the articular ligaments, causing knock-knee, painful heel, flat-foot, or lordosis, to look for stigmata of hypothyroidism, and if they are present to give thyroid extract. Whereas in children the thyroid is the great stimulant to growth, when this is complete its great function is a katabolic agent. When it is in defect there is an accumulation of the products of incomplete combustion which consequently infiltrate many tissues, including those of the central nervous system, the nasal annexes, the heart, the intestinal musculature, and the ligaments, besides the well recognized instance of the subcutaneous tissues.

Parathyroid Extract

Most authorities are now agreed that the functions of the parathyroid are distinct from, and in some respects antagonistic to, the thyroid. It increases the calcium content of the blood, thereby having a sedative effect on nervous tissues, and promoting healing from the effects of chronic sepsis (Vines). For its former action I believe it to be useful in tetany, and sometimes in petit mal. It is worth trying for fibrillary twitchings and in eclampsia. I have not been favourably impressed with its effect in paralytic agitations and other lesions of the basal ganglia. For its latter action I believe it is sometimes useful in chronic gastric ulcer, and others have found it useful in sprue and varicose ulcers. I have used it to try to check calcium drainage in diabetic ketosis, but we now have a more effective agent for this in insulin. It is apparently capable of absorption when administered by the mouth, since I have seen a rise in the calcium content of the blood following its use. It is given in doses of one-tenth of a grain once to thrice a day. There is the more justification for its use now that Collip appears to have isolated the active principle.

Adrenal Extract

There is no doubt that the medulla of the adrenals yields an intensely active extract. Although this medulla is formed from sympathetic ganglia and adrenaline produces just the same effect on any part as if its post-ganglionic sympathetic fibres have been stimulated, it has been urged that these two facts are not connected, and throw no light on the function of the adrenals. But this is pushing scientific agnosticism rather far when one remembers that the sympathetic is designed to produce widespread effects, and that these widespread effects would be assisted by the simultaneous liberation of a chemical stimulant such as adrenaline. I prefer to accept the mass of evidence which points to adrenaline as a general sympathetic stimulant which can be drawn on in an emergency. Take the case of asthma. Here is a paroxysmal spasm of plain muscle, resulting from vagal overaction, anything which stimulates the antagonist sympathetic relieves the spasm, so does adrenaline. Surely this is not merely a coincidence. There is no satisfactory evidence that adrenaline is absorbed from the alimentary tract, possibly the local vaso-constriction it excites prevents this. Thus limits its usefulness for oral administration to oesophageal spasm, gastrostasis, and the relief of vomiting in each of which it can act locally on the appropriate sympathetic endings. It can act also as a local vaso-constrictor on mucous membranes such as the

conjunctiva and the nose, and, indeed, appears to be absorbed sometimes from the latter. Injected subcutaneously or intravenously it can have a powerful effect in raising the blood pressure, augmenting the heart, relaxing the bronchial muscles, and converting glycogen into sugar. But all of these are emergency measures, and the drug is of little, if any, use in substitution therapy for the chronic adrenal lack of Addison's disease. For injection I give 3 to 5 minims for its local effects, by the mouth 10 to 30 minims of the 1 in 1,000 solution.

Although we know there is a close association between the cortex of the adrenals and the gonads, I have not seen any definite results from cortical extracts.

Pituitary Extracts

Here again we have to distinguish between two parts of the gland. The anterior lobe is concerned with growth, particularly of the skeleton, and sexual development. The clinical evidence as to this seems to me decisive, but the relative principle has not been isolated. It is usual, however, to administer extracts of the anterior lobe by the mouth for conditions of insufficiency of this portion of the gland, and it certainly appears to me to have given results. Recent observations by Gardner-Hill set off by me that anterior lobe extracts can promote growth either with or without simultaneous administration of thyroid extract, and that combined administration is more effective than that of either given separately. Posterior lobe extract has no effect on growth, but has a marked effect on stimulating uterine muscle and on the excretion of water by the kidney. Now I want to put this question forward for discussion—When we use pituitrin are we merely using a drug with known pharmacological effects, or are we, in addition, attempting to replace or reinforce the normal functions of the posterior lobe? For this question goes to the root of the controversy about endocrine therapy. Professor Swale Vincent believes we are simply doing the former. The clinician, on the other hand, believes that the pituitary has an important association with the reproductive processes, and he finds support for that belief both from clinical and experimental observations. As this is an important example of the kind of evidence we often have to rely upon in constructing a working hypothesis of endocrine therapy, I will mention some recent observations which seem to me to support the clinical contention.

Fishback's syndrome is always associated with undeveloped sexual organs. At one time I had five cases of hypopituitarism in my out-patient department associated with gross gonadal defects, either congenital or as the result of operations. Dixon showed that ovarian extract injected into the circulation produced an immediate secretion of pituitrin into the cerebro-spinal fluid. Later, in conjunction with Marshall, he showed that the presence of a corpus luteum in the ovary greatly diminished this action on the pituitary, and that, indeed, the corpus luteum of pregnancy could completely inhibit it, until just before parturition, when suddenly ovarian extract had a profoundly stimulating effect on the production of pituitrin, leading to uterine contractions and starting the secretion of milk. Mayer has confirmed these observations in human beings. Lesho Pugh has found that pituitrin will prevent a cow from holding up her milk, as she is apt to do with a strange milkman. He says "The act of milking evidently requires some sort of unconscious co-operation from the cow. This co-operation can apparently be made to be forthcoming by the use of pituitrin." He does not attempt an explanation, but it would fit in very well with an inhibition of the pituitary secretion through the sympathetic nervous system, and the replacement of the missing secretion by the pituitrin injected. Pugh also found that the failure of the corpus luteum of the cow to atrophy led to subinvolution of the uterus and disturbance of the oestral cycle. These could be rectified if the corpus luteum were extruded by manipulation per rectum. The same procedure would enable the cow to expel a mummified foetus.

Compare these observations with some clinical facts. Recently at St Bartholomew's Hospital we had a case of pituitary tumour which was associated with continuous

lactation for seven years. I have at present under observation a lady, aged 38, who was married at 21½, after this she had only twelve periods in thirteen years. She then became pregnant, and soon developed bitemporal hemianopsia. A skiagram showed an enlarged pituitary fossa. Labour had to be induced because of a contracted pelvis, but she was delivered of a healthy child and her eyesight soon became normal. She, however, continued to secrete milk for two years, although she was never able to suckle the child on account of painful nipples. The secretion stopped very soon after she was put on an extract of corpus luteum.

The most reasonable interpretation of such observations seems to be that there is a close association between the gonads and the pituitary, that the internal secretion of the ovary stimulates the secretion of pituitrin, and that the development of a corpus luteum in pregnancy checks this process, in the interests of the foetus until the time comes for the uterus to contract and the milk to flow, then this inhibition is suddenly withdrawn. Persistence of the corpus luteum prevents the proper contraction of the uterus, and an overstimulated pituitary may excite continuous activity of the mammary gland.

Then, again, the blood sugar curve of pituitary glycosuria and the glycosuria of pregnancy is the same (Wackenroth Willis), while J. H. Burn has shown that pituitrin directly inhibits the action of insulin. It suggests that the normal hold-up of pituitrin during pregnancy allows sugar to be stored more readily in the interests of the offspring through the unchecked action of insulin, failure of this hold-up to occur leads to glycosuria. By another path we come again to the conclusion that the pituitary is associated with reproduction.

Diabetes insipidus is believed to be associated with deficiency of the posterior lobe of the pituitary. I recently had a case of tuberculoma of the pituitary of which the first sign was polyuria. It is urged that this symptom is really due to disease of the overlying hypothalamus. It is extraordinary in this case that pituitrin should have such a profound antidiuretic effect even on the denervated kidney, unless one regards the hypothalamus as exerting its effect on the kidney threshold through the agency of the pituitary. I am quite prepared to agree with those who regard the hypothalamus as the head ganglion of the sympathetic system, but I should postulate that it was, like other part of the sympathetic, closely associated with the endocrine system. For this would explain Lesho Pugh's observations and would afford a close parallel with the medulla of the adrenals. But in view of the evidence I have adduced I am not prepared to agree with Professor Swale Vincent that because one can squeeze out of the posterior pituitary a juice which has certain definite actions, this throws no light on the functions of the gland. As I have said before that would be scientific nihilism. When he tells us that results of endocrine therapy are chiefly due to the influence of a credulous physician on a still more credulous patient, it is at any rate, interesting to find that similar effects have been obtained with the incredulous cow.

In passing it is interesting to note the influence of the pituitary gland over both reproductive and renal functions, in view of their close anatomical relations in the genito-urinary system.

As to methods of administration of pituitary extracts, Gardner-Hill's results justify our giving the anterior lobe extract by mouth. When there is no contraindication for posterior lobe extract I usually employ 2 grains thrice daily of the whole gland as it is cheaper. Otherwise I give only the anterior lobe extract. That the posterior lobe extract can sometimes be absorbed from the stomach is shown by Hamill's observation that uterine contractions can be produced in the cat by administration of pituitrin through the stomach tube after ligation of the pylorus. I believe that intestinal atony can sometimes be relieved by oral administration of the posterior lobe. Blumgart suggested that as the pituitary is an outgrowth of the nasal mucosa, its extracts might be absorbed by spraying into the nose or from plugs of cotton-wool soaked in a solution of the extract and inserted high up into the nasal cavity. This method has met with a fair degree of success in the

treatment of diabetes insipidus by pituitin. That intra-muscular injections of 1/2 to 1 c m of pituitin will stimulate the muscles of the heart, intestine, and uterus, and will control polyuria, is of course generally admitted.

Pancreatic Extracts

The efficacy of insulin injections is beyond doubt, but that of any pancreatic extract orally administered is quite uncertain, to say the least. Insulin is apparently contained in other animal and vegetable tissues. Its value in diabetes is generally admitted in the profession, though unfortunately much prejudice against it has been roused among the general public by the statement that if a patient once starts insulin he must take it for the rest of his life. They take this to mean that if he stops it his last state is worse than his first. This is emphatically untrue, though it is obvious that if he ceases to have it his carbohydrate intake must be more strictly controlled. It is, of course, too soon to talk of the cure of diabetes, but I have a considerable number of patients who have had a course of insulin and who are now keeping free from glycosuria and with a normal blood sugar, although they have had no insulin for periods up to a year or more. Allen has shown that persistent hyperglycaemia damages the cell islets, so that every case of diabetes must ultimately become pancreatic in character. But this does not prove then pancreatic origin, rather the reverse. I believe that our aim should be to restore a normal blood sugar early enough to prevent permanent damage to the islets, and it is therefore important to use insulin as soon as the blood sugar fails to respond to dieting. I wish to protest most strongly against irresponsible statements which lead patients to deprive themselves of the most valuable remedy which has yet been discovered for this dangerous disease.

Insulin is also being used in a tentative way for other conditions, such as hyperthyroidism, in which the carbohydrate tolerance is always lowered and the blood sugar curve rises to an abnormal height. Cramer has shown that insulin can prevent death in the experimental hypopyrexia produced by tetrahydrophthylamine, which excites metabolism certainly suggests its use, together with dextrose, in hepatic toxæmias with ketosis. For in this way we can assist in the complete oxidation of the fats which are producing the toxic anabolic bodies.

Other Extracts

Of other extracts I need say little. I am hopeful about ovarian extract now that it has been shown experimentally to produce definite effects, and that Allen and Doisy have prepared an extract which will produce oestral phenomena in oophorectomized animals. It ought, therefore, to be possible to place an active extract on the market, and the unreliable character of many of the commercial products may be due to their preparation from ovaries containing a corpus luteum. Even as it is I believe I have seen benefits following administration of ovarian extract, though it happens that all my positive results have been obtained with one particular preparation. If we could do something to alleviate the misery which the climacteric woman suffers herself and inflicts upon others we might bring peace into many households. But my best results have hitherto been obtained in cases of ovarian inadequacy in earlier life. Successes have been reported with extract of corpus luteum, for the use of which there seems to be some rational basis.

I am sceptical about the efficacy of any orchitic extract given by the mouth. Here the grafting method offers a better chance.

Although the thymus appears to have a real retarding effect on sexual maturity, it does not appear to do so by virtue of an endocrine secretion as ordinarily understood. So there is no rational basis for the administration of thymic extract.

The pineal body would appear to produce its effect through the nervous system and not as an endocrine gland, so little is to be expected from pineal extract in sexual precocity and muscular dystrophies.

I am entirely sceptical as to the value of extracts other than those I have mentioned.

II—SWALE VINCENT, LL.D., D.Sc., M.D., FRS ED., FRSC SV

Professor of Physiology, University of London (Middlesex Hospital Medical School)

I HAVE, on previous occasions, attacked the wholesale uncritical employment of animal products as drugs. But the enemy's line is not yet broken and the sale of worthless preparations goes on apace.

The history of organotherapy has now been recorded several times, and, amusing as it might be, I do not think it would serve any useful purpose to recapitulate this chapter on the present occasion.

The word "endocrine" has come into use as a synonym for "internally secretory," so that it is now customary to refer to "endocrine glands" and "endocrine therapy." It follows that in the latter case we are not concerned with treatment by animal tissues in general or even by glandular extracts as such. It is only when we are able to institute a true substitution therapy—artificially to replace the internal secretion of some ductless gland—that we have a right to use the expression "endocrine therapy."

In the advertisement pages of our journals we find a long list of "endocrines," singly or in mixtures. It is assumed by the advertisers, and is apparently accepted as an axiom by the physicians who prescribe these products, that they will bring about their beneficial results when they are given by the mouth. It is on this point that there is the greatest difference of opinion. It is universally recognized that thyroid gland and its various preparations are effective when given by the mouth. It is also generally admitted that insulin is not of any therapeutic use when orally administered. In regard to all the rest, a score or so of much-puffed preparations, there is very considerable doubt. Preparations of parathyroid, pituitary, and others are believed by many to be effective when given by the mouth, while the rest are only prescribed in this manner by the most optimistic and uncritical. It is to be noted, however, that this group includes a very large number of individuals.

Some recent reports by responsible writers express considerable doubt as to the value of parathyroid extracts when given by the mouth. According to the statements of numerous writers the preparations given in this way are useful in parathyroid deficiency, nervous disorders, calcium deficiency, chronic toxæmias, etc. Many physicians prescribe small doses of adrenin to be taken by the mouth, though others express doubt as to the efficiency of this proceeding. The pituitary substance, various pancreatic preparations, extracts of ovary, corpus luteum, and mammary gland, are frequently given by the mouth and good results are reported by some observers. Oral administration of orchitic extracts is generally admitted to be useless. Among other organs and tissues extracts of which are administered by the mouth, we need only mention thymus, pineal body, liver, spleen, kidneys. There is not the slightest reason to believe that these have any action in health or disease, and the same applies to still other substances which are advertised by the manufacturers of endocrine products.

The difficulties surrounding the subject of endocrine therapy are of two kinds. In the first place, there is the difficulty, common to all branches of therapeutics, of deciding for or against the value of a drug. It is useless to claim that a drug has done good unless we have a moderately clear idea of what was going to happen if nothing had been done. This very obvious consideration is almost universally overlooked even by medical men. The public has not yet even begun to grow suspicious. It swallows gillons of medicine in blind faith, trusting either to the blatant advertisement of the drug vendor or to the trust-inspiring manner of the practitioner. Many of the patent medicines are devised for spasmotic conditions which usually only last for a limited period, after which the patient may be fairly well until the next attack. Such conditions as asthma and epilepsy. It is obviously very easy to establish a reputation for any remedy in these disorders, and I suppose there are more "cures" for these than for any other diseases, if we exclude coughs and colds. It is clear that we must make great efforts to distinguish between *post hoc* and *propter hoc*. Some sort of experiment

must be carried out. Rigid and adequate controls must be instituted.

But there is another kind of difficulty connected with endocrine therapy. This depends on the fact that treatment by gland extracts is based so largely on *a priori* or on theoretical considerations. The widespread employment of endocrine therapy is based upon the theory that all organs and tissues in the body manufacture and pour into the circulation some kind of internal secretion whose function it is to influence some special or the general metabolic activities of the body. If there be a deficiency in any one of these, what could be easier than to replace it by the administration of extracts of the appropriate gland? This, the generalized theory, has many ramifications. The whole story of vagotonia and sympathetotonia and the division of glands into "sympathetotropic" and "parasympathetotropic" is based upon the assumption that the secretion of the chromophil tissues maintains the tone of the sympathetically innervated tissues. The argument put forward is that, since adrenin acts as a tonic continuous stimulus to the sympathetic system, there must be some substance which performs an analogous function for the cranial and sacral autonomic fibres. Now it is difficult to adduce any satisfactory evidence that the chromophil tissue has the function alleged, or, indeed, that it is of any service whatever in the normal state of the animal. The discharge of adrenin from the adrenal body is not indispensable for life or health, and there is, indeed, no reliable evidence that under normal conditions the circulating blood contains any adrenin at all. It follows, then, that the argument for the existence of "autonomin" or "hormone X" by analogy with the function of adrenin, falls to the ground. It is not clear why it should be necessary to assume that "there is some substance which exerts a continuous stimulating action upon the autonomic nervous system." Why do we not make the same assumption for the tonic influence of the spinal cord upon the skeletal nerves? Why not assume that the inhibitory and other influences of the cerebium upon the lower centres are controlled by a special hormone?

But many physicians have not claimed, or have ceased to claim, that their endocrine practice is based on sound physiological data. They insist, however, on the value of endocrine extracts, urging that, although they may contain no physiologically active principles, they are found empirically to do much good in various diseases and disorders. There can be no objection to this attitude, but it is only reasonable to urge in the strongest possible terms that the *a posteriori* evidence of relief or cure must be satisfactory. In many instances this is far from being the case. All the old stumbling blocks trip up the unsuspecting physician, all the fallacies effectually deceive him. He tumbles into all the "pitfalls." The difficulties referred to above are not realized and so are not circumvented, and the scientific value of any conclusions which may be drawn is nil.

As we have already seen in regard to the great majority of endocrine products (in fact all except one) as sold by the manufacturing druggists, there is no satisfactory evidence that any effects whatever are produced in healthy animals when they are given in the ordinary way by the mouth, unless they are given in such quantities as to serve as foods. On previous occasions I have expressed the opinion that "it would be difficult to mention a drug which is clearly and beyond doubt of value in the treatment of disease and yet which produces no recognizable pharmacodynamical effects upon a healthy animal." I suppose that in the case of the majority of drugs of mineral or vegetable origin it would not nowdays be expected that a substance incapable of inducing any changes in the condition of a normal animal would still be of value in the treatment of disease. But if non or substances yielding vitamins be given with the object of replacing these substances which are lacking in the diet, I suppose it might be expected that little or no effect would be produced by their administration to a normal individual. The same kind of argument might be used in the case of the active principles of the internally secreting glands, when they are administered in accordance with the theory of "substitution therapy." In animals or in human beings suffering from insufficiency of secretion of a gland good results might accrue from an extract of the gland in

question, while in a normal individual little or no effect might be observed. It is said that parathyroid grafts will not "take" unless a parathyroid deficiency has been induced either by disease or operation, and that parathyroid feeding diminishes the guanidine and increases the calcium in the blood in certain diseased conditions. The most recent preparations of parathyroid gland are stated to have a powerful effect upon the normal animal—when subcutaneous injections are employed.

It must, however, be remembered that insulin, adrenin, and thyroid extract have a powerful effect upon the normal animal. It will, then, not be unreasonable to regard with considerable suspicion the report that a pharmacologically inactive substance is of therapeutic value. But it must be admitted that one ought to exercise considerable caution in procuring any substance to be pharmacodynamically inactive. The action of such materials as meat extracts is often as pronounced as that of tea and coffee, yet no one even regards the former as drugs, while the latter are universally placed in this category. Again, we must not lose sight of the fact that we have no right to affirm that a drug has no physiological action simply and solely because, when a dose is injected into the vein of an animal, there is no noticeable effect on the blood pressure, respiratory movements, or flow of urine. There are several other kinds of pharmacodynamical actions which the researches of recent years have made it necessary for us to take into consideration. Possible effects on the blood sugar and on the basal metabolism should not be forgotten.

Although extracts made from the majority of organs and tissues produce no noticeable physiological effects when they are given by the mouth, yet when they are injected beneath the skin, or especially into the blood stream, some influence on the organism may be produced. Thus, tissue extracts in general, when injected beneath the skin of animals such as dogs and cats, have a slight but quite recognizable stimulant or irritant action. When the extracts are injected into the blood stream there may be distinct physiological effects, such as, and in particular, lowering of the blood pressure. It cannot be urged too strongly that these effects are not specific, and have nothing to do with any internal secretion on the part of the tissue in question. To argue that because extracts of the cerebral cortex lower the blood pressure, it is therefore one of the functions of the cerebral cortex to manufacture and pour into the circulation a "hormone" whose duty it is to keep down the blood pressure, would be absurd. Yet an assumption almost as unjustifiable has been made in respect of those few tissues whose extracts contain a substance which raises the blood pressure. But every few months articles appear which show that it is still necessary to point out what I showed for the first time many years ago, that tissues generally contain a depressor substance, and that there is no reason to believe that this fact has any bearing on the subject of internal secretion. The substance in these extracts which lowers the blood pressure has by some been supposed to be choline, by others histamine. It appears to be neither of these, though its real nature is yet unknown. There may, of course, be several such substances, some or all of them are soluble in water, alcohol, and ether. There is, of course, no proof that these substances are not the active principles of the glands, the point is that it is not by virtue of their action on the blood pressure that they may be recognized. These physiological actions, although they are sometimes ascribed to a specific "hormone," are not generally correlated with a therapeutic action, for they are usually not known to the "clinical endocrinologist."

The method by which extracts are prepared is a matter of supreme importance. In the first instance it was customary in laboratory work to cut up the tissue into small pieces or press it through a mincing machine, and then pound it up with sand and normal saline solution. The extract could then be used after filtering, or it might be boiled with a trace of acetic acid and then filtered. In the former case we had a "protein extract" in the latter a "protein free" extract. Sometimes alcohol or ether or some other extrahent is used but the final product should, of course, be dissolved in normal saline solution before being injected into an animal. This condition is of course, not essential if the preparation is to be administered by the mouth. Many

commercial preparations, if not the majority, are made by simple drying and powdering the tissues, either in their natural state or after removal of the fats (and lipoids?). By such means it is certainly possible to get active extracts of thyroid, adrenal, and the pituitary, but it appears from recent work on the pancreas (vide infra), the ovary, and the parathyroid, that in the case of other organs and tissues special modes of preparation may be necessary. There is great danger that, in the attempt to prepare a clean, "elegant" preparation, whatever active principles are present may be destroyed.

Thyroid Medication

Thyroid preparations are universally recognized as ranking with our most valuable drugs, and it is not an insignificant circumstance that they are potent when given by the mouth. According to Kendall, the active principle, thyroxin, is 4,5,6-hydro-4,5,6-iodo-2-oxy-beta-indol propionic acid. It is not quite certain that thyroxin represents the whole of the active material of the thyroid gland.

Various thyroid preparations are in regular use in medicine. Dried thyroid substance is perhaps the surest and most popular. The best indication for thyroid treatment is a low basal metabolism. When this is found we have an intelligent reason for the thyroid administration, and every hope of success. But a drug which increases the total metabolism of the body may be useful in a great variety of disorders. It is advertised as good for asthma, constipation, enuresis, epilepsy, defective development, haemorrhage, infectious diseases, obesity, rheumatism, senility, skin diseases, toxæmia, and in so far as any of these, notably obesity, may be due to a sluggish metabolism the treatment may be beneficial. Thyroid substance is present in many of the combinations of "endocrines" on the market, and most often is the only ingredient which has any effect at all when given by the mouth.

Parathyroid Medications

We do not yet know what is the function, or what are the functions, of the parathyroid glandules. The intoxication theory of Koch, Paton, and others, and the calcium regulation theory of McCallum and Voegtlin, do not appear to stand in any relation to each other. The guanidine intoxication theory is opposed by Greenwald on chemical grounds. Most of the recent work has been devoted to the relation of the parathyroids to calcium metabolism. The results of parathyroid medication are still very uncertain. It is difficult to state in exactly what morbid conditions one would expect it to be of use. Tetany, the result of disease or damage to the glandules, is, of course, one such condition, but there has been too great a hurry to assume that all kinds of "tetanic" disorders are due to parathyroid lesion or dysfunction. It is by no means certain that any form of tetany is connected with the parathyroids except, indeed, that which sometimes occurs when the glandules are injured or removed during operations upon the thyroid. Other forms of tetany are due to a great variety of causes. Thus we have the idiopathic tetany of workmen, maternity tetany, gastric tetany, tetany in infection and intoxication, post-operative tetany, and tetany after forced respiration. It is not to be assumed without further evidence that all these forms are due to disease of the parathyroids. It seems reasonable to suppose that a great many different conditions may give rise to the phenomena of "tetany." It has recently been shown that administration of thyroid substance to animals will frequently produce this condition. Parathyroid insufficiency has also been suspected to be the essential pathological condition in paralysis agitans. But hyperfunction has also been alleged to occur in this disease, and the majority of observers fail to find any connexion between the parathyroid glandules and the disease in question.

It is exceedingly doubtful whether any parathyroid preparations at present on the market will, when given by the mouth, even relieve the symptoms due to injury to or extirpation of the parathyroid bodies. The majority of competent observers find these preparations to be physiologically inactive and useless as therapeutic agents. In the case of the parathyroid, the ovary and the pancreas, some special method of extraction is required in order

to obtain preparations which display any physiological activity. According to current views, all the internal secretions must be soluble in or extractable by water. But some of them seem to occur in the glands in combination with lipid substances, and it is necessary to break up this combination in order to get the substance into watery solution.

Collip claims that he has extracted from the parathyroid a principle which, on injection, prevents tetany for thirty hours in parathyroidectomized animals. This substance also produces a very marked increase in the blood calcium. One of the most interesting items in Collip's communication is the statement that his extract is effective when administered by the mouth. He states most emphatically that he obtained negative results from all the commercial preparations he was able to test. These results have been in the main confirmed by Cameron.¹ It would seem that this work marks a distinct step in advance, but the problem of the parathyroids is not yet solved, and it is by no means clear in what cases the administration of a calcium-increasing drug is indicated. The estimation of the blood calcium is by no means an easy matter as a routine practice, and the pathological conditions in which the calcium is below par are not yet known with any degree of certainty.

Parathyroid treatment has recently been recommended for the treatment of sprue. Scott reports excellent results after administration of parathyroid and calcium lactate. The blood calcium increased in accordance with the general improvement of the patients, but there is no statement that the author has tried the effects of calcium lactate without the parathyroid. It is, at any rate, not surprising to find that the administration of a salt of calcium may lead to an increase in the calcium content of the blood.

Returning for a moment to the subject of tetany, it is reasonable to hope that any cases of tetany in the human subject which may be due to parathyroid deficiency may be treated with success by the substance of Collip. We must, however, bear in mind that tetany in animals due to extirpation of parathyroids frequently disappears and leaves no traces even when no active treatment is carried out. This frequently occurs in monkeys, especially if they are kept on a milk diet. Tetany is probably due to many different causes, and many different modes of treatment have been found to be beneficial.

Pituitary Medication

It is not yet possible to say what is the function of the pituitary body. The structure is composed of several parts, differing in origin, in structure, and presumably in function. It is, perhaps, in the case of this organ that the greatest confusion has arisen between pharmacodynamical action and the evidences for internal secretion and the basis for a true "substitution therapy." There is no doubt that posterior lobe preparations contain principles which will raise the blood pressure and increase the flow of urine and produce other effects when injected into the circulation of an animal. There is also no doubt that posterior lobe preparations are useful as drugs (when injected subcutaneously) in the treatment of diabetes insipidus and to aid the contraction of the uterus. They are also valuable in meteorism. But it is very doubtful whether these actions and these uses have any relation to any known functions of the organ. We have, in all probability, no right to regard them as instances of "substitution therapy."

Adrenal Medication

Adrenin, the active substance obtained from the chromophil tissues, sold under various names, has pronounced physiological activities (when injected into the circulation, or applied to mucous membranes) and is a very useful drug. But at the present time it is difficult to correlate this action and this usefulness with anything we know about the functions either of the adrenal body or of the chromophil tissues. Here, as in the case of the pituitary extracts just referred to, there is in all probability no question of a "substitution therapy." A study of the chemical nature of the active substance of the chromophil

tissues has led to the employment of certain amines as drugs. It is generally conceded that adrenal preparations have no effect of any kind in health or disease when they are given by the mouth.

Several years ago I fed a hungry dog with the adrenal bodies of a whole flock of sheep, and no effects could be observed except those of repletion. Further, I administered to an adult male human volunteer huge doses of dried adrenal medulla without the slightest effect on blood pressure, respiration, urino, etc. It is, of course, possible that there might have been slight changes in metabolism which could be detected in more modern times.

A possible exception may be admitted owing to the local action of adrenin on the lining membrane of the stomach. But Leyton states that adrenal extract given by the mouth will raise the blood pressure in cases of Addison's disease, and Hitchcock has recently affirmed that adrenin given by the mouth raises the metabolic rate. These statements, however, have not been confirmed by other observers.

Testicular and Ovarian Medication

Extracts made from testis and ovary have not been found to produce any effects either in health or disease when given by the mouth. But in 1914 Heilmann and Frenkel prepared an active substance, sold by a firm in Basle, and Allen, Doisy, and others claim that they have, by practically the same method, extracted "the principal ovarian hormone." The residue from an ether extract is treated with acetone, which throws down an inactive precipitate. The filtrate contains the active substance, and after being once more taken up in alcohol and evaporated to dryness the minute yield of oily residue is dissolved in corn oil for injection. The extracts are tested by noting the effects on spayed animals. In 1917 Stockard and Papanicolaou described a method for following the oestral changes in the living animal. During the anabolic phase of the cycle in the guinea-pig, the rat, and the mouse, the vaginal epithelium grows and a cornified layer appears. During the katabolic phase the outer layers of the epithelium degenerate and are removed by leucocytic action. These changes show a regular succession of cell types in the vagina, each one characteristic of a certain phase of the cycle. In this way the microscopical examination of vaginal smears becomes an indication of the oestral condition of the animal.

According to Allen and his co-workers, injections of the extract into animals from which the ovaries have been extirpated produce not only the typical hyperaemia of oestrus, but also hypersecretion in the genital tract and growth of the mammary glands. There is the thickening and cornification of the vaginal walls and subsequent degeneration. Moreover, the animals will admit the male during the artificial oestrus. No positive results were obtained with commercial extracts nor were there any effects from oral administration. Several years ago Marshall and I made extracts from oestrous ovaries and injected into a bitch at a period remote from the oestrous one. In some instances a swelling of the vulva and other slight signs of the oestrous condition were induced. The results obtained by Allen and Doisy have been fully confirmed by Wright, Dodds, and Dickens, working in the physiological and biochemical laboratories of the Middlesex Hospital. They find that no active substance can be extracted from any of the commercial preparations which they have examined. The yield of active material is exceedingly minute. No effects are observed when the material is given by the mouth. Testicular extracts do not appear to be of any value when administered by the mouth. The only possible method of instituting a true substitution therapy in the case of the testis appears to be by grafting, and it cannot be said that this proceeding has proved itself entirely satisfactory.

Pancreatic Medication

For a long time physiologists and physicians have been firm in their belief that the pancreas has, in addition to its work as a digestive gland, the function of pouring into the blood stream some substance the absence or deficiency of which produces diabetes in animals (and most probably

also in human beings). Many attempts have been made to remedy the deficiency by administration of pancreatic substance. The majority of those working at problems of internal secretion must have tried the effects of treating diabetic patients with minced raw pancreas (a method which is being revived at the present moment), and most have come to the conclusion that the method is impracticable, although in a few cases some benefit would seem to have accrued. It is only within the last three years that a preparation has been made from the pancreas by Banting and Best which can be relied upon to reduce the blood sugar in normal and depancreatized animals and in human beings suffering from diabetes. There are now several different ways of preparing insulin, and it (or a substance having an identical or very similar pharmacodynamical action) may be obtained from many organs and tissues, animal and vegetable, although in greatest amounts from the islets of Langerhans in those species in which islet tissue can be procured separate from the rest of the pancreas, as in some teleostean fishes. The substance, whatever may be discovered as to its chemical nature, appears to originate in the body chiefly from the modified pancreatic tissue which forms the islets of Langerhans.

Insulin ranks with thyroid substance as a means of employing a very valuable substitution therapy. Although the best known and most reliable preparations have to be given by subcutaneous injection, several observers claim that their special substances are effective when given by the mouth.

Summary

The present summary is only slightly modified from that given in March of this year.³

There are yet only two clear cases where we can employ a true substitution therapy—those of the thyroid and the pancreas, of these only one, the thyroid, is known to produce any effects when given by the mouth. Some observers claim that certain pancreatic extracts may be efficacious when given in this way.

It may be that sooner or later we shall be able to include the parathyroid and the ovary in the same category, though, according to the best evidence, the preparations of these organs which are commonly employed are inactive, and the recent products made by special methods must be given by hypodermic injection.

The internal secretion of the testis may possibly be restored or reinforced by grafting.

There are, however, two striking instances in which substances obtained from organs usually supposed to furnish internal secretions are valuable as drugs, apart altogether from the question of internal secretion and substitution therapy. These are adrenin and preparations made from the posterior lobe of the pituitary body. And it is very doubtful whether any of these have any effects when administered by the mouth.

Thus out of the long list of organs and tissues advertised by the manufacturing druggists and prescribed by the clinical endocrinologists to be administered in the ordinary way by the mouth, only one—the thyroid—is of proven value.

III—H GARDINER-HILL, M.B., M.R.C.P.,
Medical Unit St Thomas's Hospital

As my contribution to the discussion I would like to give a brief account of some of our experiences with endocrine therapy in the Medical Unit at St Thomas's Hospital. Our attention has been chiefly directed to the uses of thyroid, pituitary, ovarian, and orchic extracts, and we have attempted to control our clinical observations by the metabolic tests to which Dr. Langdon Brown and Professor Swale Vincent have already referred.

In the first place, I would like to discuss the value of thyroid extract in obesity, and to call attention to the way its action can be augmented in certain cases by the simultaneous administration of whole-gland pituitary extract. We have found this method of treatment especially useful.

* Be t Smith and Scott have however shown that insulin can be obtained from the tissues of a dog which had been depancreatized some weeks previously, and Baler Dickens and Dodds report an abundant amount of insulin in the tissues and pancreas of a patient who had died in diabetic coma.

not only in the obesity of adolescence of the so called pituitary type, but also in adults, and especially in females where obesity developed after childbirth or at the menopause. In some of these patients thyroid extract is quite effective when given by itself, but in others thyroid intolerance soon develops. It is in these circumstances that pituitary extract is useful, though in the present state of our knowledge it is difficult to offer an explanation of its action. We have found, however, that estimations of the sugar tolerance in patients under treatment throw some light on this question, and enable a distinction to be drawn between the two groups of cases.

In the normal person, after 50 grams of glucose the blood sugar rises from a fasting level of 0.1 per cent to about 0.175 per cent at the end of half an hour, and then falls again to the fasting level by the end of an hour and a half. In patients with obesity the response to sugar is different—two types of curve are found. In the cases of recent origin there is an inability to deal with sugar, the curve is high and prolonged, and the sugar tolerance decreased, in the later cases sugar is dealt with too quickly, the curve is low, and the sugar tolerance increased. It is in the latter group that thyroid extract is effective when given alone, and these patients show little tendency to thyroid intolerance. In the earlier cases, however, with decreased tolerance, thyroid extract appears to reactivate the delay in the curve and cause hyperglycemia. Whole-gland pituitary extract, given by itself, has an opposite effect on the blood sugar tolerance curves of these patients to that of thyroid extract, the carbohydrate metabolism is improved and the sugar tolerance increased, but this is not accompanied by loss of weight. It may be recollected that this agrees with Burn's observations that pituitary extracts have a stabilizing effect on the blood sugar.

Now the point I particularly wish to call attention to is this: by administration of thyroid and whole-gland pituitary extracts simultaneously the beneficial effects of thyroid extract can be obtained without its attendant disadvantages, and a considerable improvement in metabolism and loss of weight occurs. This improvement in metabolism, however, is not maintained for any length of time when treatment is discontinued, sooner or later it reverts to its former state and the patients again gain weight. It does, however, seem possible, when once the weight has been reduced, to maintain the new level of metabolism on decreased doses, and by on and off treatment to help these.

This seems to be a point well worth taking into consideration when the tendency of obese people to become diabetic is remembered, and I have drawn attention to the fact that sugar tolerance estimations in these patients show that many of them must be regarded as potentially diabetic.

The details of these investigations are being published in full elsewhere in conjunction with Dr Forest Smith and Dr Isaac Jones. It will suffice here to point out that desiccated extracts of thyroid and whole-gland pituitary are used and given in doses gradually increased at fortnightly intervals, starting with half a grain of each a day and working up to a point where the patient loses one or two pounds a week. Estimations of the sugar tolerance are made at frequent intervals to control the dosage.

This method of administering thyroid and pituitary extracts simultaneously we have also made use of in certain cases of adolescent goitre. Pituitary extract by itself has no apparent effect on these goitres, if given with thyroid extract the beneficial effect of the latter seems to be enhanced. Marine and others are of the opinion that they can be prevented by the prophylactic administration of iodine to school children, this is now generally accepted, but it is a different proposition when the goitre has actually developed. In these circumstances, in our experience, iodine administration does not appear to be very effective, either in reducing the goitre or in regulating the metabolic disturbance which is sometimes associated with it. Many of these goitres are unaccompanied by any other sign of disturbed thyroid function, and they disappear in time entirely of their own accord. This seems to be especially true of those developing before the onset of menstruation, but in a series of 100 cases we have recently investigated

a considerable proportion of those developing subsequently to the onset of menstruation showed evidence both clinically and by metabolic tests of disturbed thyroid function. In 32 per cent there appeared to be a tendency to hyperthyroidism, and in 26 per cent a tendency to hypothyroidism, and it is particularly in the latter group that thyroid extract, given in conjunction with pituitary extract, is valuable in reducing the goitre and in regulating the associated metabolic disturbances. This method of treatment appears to be equally successful in reducing many of the physiological goitres first mentioned.

I would like to refer next to the value of thyroid and pituitary extracts in the treatment of undergrown children, and particularly to mention the results we have obtained by giving anterior lobe pituitary extracts by themselves. The effect of thyroid extract on the rate of growth of thyroid-deficient children is well known, the rate of growth can be considerably increased. As an instance, I will cite the case of a girl with juvenile myxoedema, whom we have been treating for the past three years. Her rate of growth on thyroid extract is more than five times as great as her rate of growth when this treatment is discontinued. Thyroid extract is equally effective in increasing the rate of growth of less obviously thyroid deficient children, and in this connection metabolic tests are valuable in picking out the cases which are suitable for treatment.

The value of anterior lobe pituitary extract given by the mouth is not generally appreciated. Dr Langdon Brown has already referred to our observations on two infantile children whose rate of growth and carbohydrate metabolism have been considerably increased by this means alone. These children have now been under treatment for a year, and their rate of growth has been accelerated from 3.5 and 3.6 cm per annum to 6.4 and 7.5 cm per annum respectively—then rate of growth has been doubled. We have at the present moment a series of seven children under treatment with anterior lobe pituitary extracts in whom sugar tolerance estimations have been carried out at repeated intervals during treatment. Before treatment they all showed an inability to deal with sugar, the sugar tolerance was decreased. Feeding with anterior lobe pituitary extracts has greatly increased the sugar tolerance in every case. The average blood sugar figure of the seven at the end of one and a half hours after 50 grams of glucose before treatment was 0.159 per cent, representing a considerable delay in the curve. The average figure of the seven at the same stage after treatment was 0.104 per cent, this represents a normal curve. This is difficult to explain, except on the assumption that the extracts are active. We have also several children under treatment with combined thyroid and anterior lobe pituitary extracts, and the resulting increase in growth is greater than in the cases where either of these extracts have been given alone. Estimations of the sugar tolerance again show that in these children also the carbohydrate metabolism is considerably improved by treatment.

Finally, I would like to refer to our experiences with the at present available ovarian and orchic extracts. The results have been entirely negative, except, possibly, in the case of extracts of the corpus luteum, but we have had a number of cases, about twelve in all, of primary and secondary amenorrhoea under regular treatment with various extracts of ovarian substance and ovarian residue for some four to six months. In some of these patients the dose has been worked up to as much as 45 grains of ovarian extract a day, but in no case could any effect be attributed to this treatment—there was no alteration in weight and menstruation was not influenced in any way. Orchic extracts have been equally unsuccessful in influencing the metabolism of male eunuchs.

In conclusion I would suggest that thyroid and pituitary extracts have proved extremely useful in certain cases of obesity, adolescent goitre, and defective growth, especially when given simultaneously. Our results also show that anterior lobe pituitary extract, when given by itself, has an influence both on growth and carbohydrate metabolism. On the other hand, the at present available ovarian and orchic extracts have in our experience proved entirely useless.

IV—KENNETH M WALKER, FRCS,

Lecturer in Venereal Diseases, St Bartholomew's Hospital

I SHALL confine my remarks to what I may call the surgical aspect of endocrine therapy—that is to say, to attempt to remedy deficiencies in the endocrine system by means of grafts. These attempts have been rendered necessary through the failure, except in the case of the thyroid and the pancreas, to obtain an effective extract.

Before discussing the matter in detail it will be useful to formulate certain general principles underlying the use of transplants of any living tissue. The first of these is that the more closely related the donor of a graft is to the host the more likely is the graft to survive. Indeed, it may be said that at the present day the only way in which grafting can be accomplished with anything like constant success is by the use of "auto grafts"—that is to say, of material taken from the host's own body. As an example of this may be quoted the general failure to avoid symptoms of the menopause, in patients in whom an oophorectomy has been performed, by the use of "hetero grafts," but the success that attends the use in such cases of auto-transplants. Even when we confine our attention to "homo grafts"—that is to say, grafts taken from a member of the same species—the same rule concerning the relationship of the donor to the host holds good. Thus it has been found in animal experiments that better results are obtained with transplants from a brother or sister born in the same litter than with grafts derived from a less closely related donor. When donors of a different subspecies or species are employed the absorption of the graft is so rapid that the operation is useless. Indeed, it is probable that in human surgery the use of grafts obtained from such animals as a sheep or a goat is no more effective than the employment of injections of emulsified gland. This being so, if tissue from the lower animals is to be used it is better to follow the technique of Stanley and Keller and inject fragments of solid gland through a large calibre needle rather than to perform an open operation. The action of a hetero-graft is, in my opinion, entirely due to the absorption of a certain amount of active principle during the process of disintegration. Voronoff has, of course, in his work on testicular grafts, made extensive use of monkeys, and has justified his choice on the ground that man and the anthropoids are very closely allied in their serum reactions (both agglutination and precipitation). But while I agree with him that it is better to obtain grafts from the higher than from the lower branches of the monkey family, I am convinced that in any case a rapid absorption of such grafts must occur. It is, indeed, my belief that the only hope of effective work in endocrine transplants lies in the obtaining of material from a human source. This, of course, is a matter of difficulty. Perhaps I may appeal to those who have cases of ectopia testis in which orchidectomy is contemplated to allow me the use of this material, for at present my work is entirely held up for lack of grafts.

This question of the absorption of grafts is of such importance that it must be discussed in greater detail. In this connexion Loeb's intensive study of the reaction of a host to a graft is of special interest. By removing grafts at different intervals after transplantation into animals Loeb showed that in their disappearance two distinct processes are at work. The more important of these consists in the development of connective tissue within the graft, causing a gradual strangulation of the blood supply. The second process is an invasion of the graft by leucocytes. The leucocyte in this case apparently acts as a primary destructive agent, and not merely as a scavenger of disintegrating tissue. Loeb considers that the connective tissue proliferation and leucocyte invasion are due to changes that have occurred in the metabolism of the graft cells, and that they are not the result of any primary hostile reaction on the part of the host. The altered metabolism in the graft gives rise to toxins, which in their turn attract leucocytes and bring about a change in the activity of the connective tissue cells of the host. The more distantly related the donor to the host the more active is this formation of toxins, and the more energetic the subsequent invasion by leucocytes and connective tissue cells.

It must, however, be remembered that there are other

factors besides the relationship of the donor to the host that determine the rate of disappearance of a graft. It has been found that different tissues vary greatly in the rapidity with which they are absorbed. As an example of this may be quoted Christmann's experiments on suprarenal grafts in rats. These experiments showed conclusively that whilst the cortical layer of the suprarenal may survive in a transplant for a considerable period, the medulla rapidly disappears. In his experiments Christmann removed one of the two suprarenals of a rat, and after dividing it into several pieces placed it within the peritoneum. In from one to six days the grafts had become enveloped by omentum and a penetration of the periphery of the graft by new blood vessels had occurred. *Pari passu* with this vascularization there took place a regeneration of the cortical layers and an entire disappearance of the medulla. While, therefore, it is possible to transplant the cortex of a suprarenal, it is not possible to graft the medulla, even if the graft be an auto graft.

It will be seen that the factors hitherto mentioned as influencing the survival or disappearance of a graft are factors depending on the graft rather than on the host. In other words, it is the metabolism of the invading cells, rather than a hostile reaction on the part of the host that brings about the disappearance of the engrafted tissue. There remain, however, to be considered other factors that are dependent on the host. Halstead has stated that grafts do not ordinarily survive unless there is a pre-existing physiological deficiency in the host of the gland in question. For example, transplants of testis will only succeed in cases of eunuchoidism. Should the animal be fully sexed the grafts will not survive. Still less is a graft capable of surviving when it is exposed to the action of an opposing gland. Thus Steinach found in his masculinization and feminization experiments that it was impossible to engraft an ovary on a male rat or a testis on a female unless the animals had previously been castrated.

Summarizing the foregoing we see that the rapidity with which a graft is absorbed depends partly on the nature of the graft and partly on the state of the host. The factors connected with the graft are the type of tissue employed, and the age and relationship of the donor to the host. The factors depending on the host are the existence or non-existence of a deficiency in the gland engrafted, and the absence of any antagonistic force exerted by an opposing endocrine gland.

The actual technique of grafting is a surgical question which need not be considered here in detail. The essential for success is that the graft should be favourably placed for the earliest possible vascularization. The sites that have been employed are in the rectus sheath, in the spleen, within the bony medulla, and in various positions within and beneath the peritoneum. In the case of testicular grafts I have always, where possible, employed the cavity of the tunica vaginalis. The advantage of using a serous cavity of this nature is that subsequent to the operation the graft becomes bathed in an inflammatory exudate which is highly nutritive in nature, and provides nourishment for the graft until vascularization has occurred. Asepsis and haemostasis are, of course, essential to success.

In interpreting the results obtained from grafts it is necessary to maintain a strictly critical attitude. In my own work on testicular grafts I have supplemented clinical observations by sugar tolerance and basal metabolism tests carried out before and after operation. Only where definite changes were found, not only in the clinical condition of the patient, but also in his laboratory tests, have I assumed that the graft had exerted any effect. And even when an effect has been demonstrated, it must be remembered that the life of the graft, except possibly in the case of an auto-graft, is a limited one, and that sooner or later, and almost certainly within the space of three years, all the transplanted tissue will have disappeared. And what is true of testicular grafts is equally true of transplants of other endocrine glands. Kocher, a pioneer in thyroid grafting, gave it as his belief that it is not possible to obtain permanent relief by such methods.

Turning to glands other than the thyroid and the gonads, the results of transplantation will be found to be still less favourable. In the case of parathyroids, whilst

auto-transplantation, in dogs in whom a definite parathyroid deficiency had been occasioned, is successful, the results of homo transplantations in the same animals are very unreliable. I have found no cases recorded of successful grafting of parathyroids in the human being. Suprarenal grafts, whilst they have succeeded in prolonging life in animals, have invariably been unsuccessful in man. Nor have any permanent results been obtained from the use in human surgery of pancreatic or renal transplants, although in both cases temporary benefit may have been noted during the period of disintegration.

Yet it is difficult to feel that grafting has no future. Progress in the culture of tissue *in vitro* and in the knowledge of the laws governing the growth of cells, further information concerning the action and retention of engrafted tissue and host, and of one member of the endocrine circle on its neighbour—these are the lines along which an advance must be made. Then when these difficulties depending on the interaction of the transplanted cells and the host's tissues are understood, and the factors that contribute to the rapid absorption of grafts reduced or eliminated, there is no limit to the aid that the surgeon may lend to the endocrine therapist.

V—H W C VINES, M D, Cambridge

WE have before us two papers of considerable interest, not so much perhaps as regards the matter they contain, as the outlook of the two writers upon the matter under discussion. The paper by Dr Langdon Brown is an account largely of the experiences of the writer in the clinical usage of endocrine substances, that by Professor Vincent suggests rather the statement of a preconceived dogma, unalterable by the progress of the investigations of others, and unsupported by recorded experiences of the writer, nor does there appear to have been any effort to test experimentally the validity of the theme which runs through it, that all endocrine therapy is useless with the exception of thyroid and perhaps pancreatic extracts.

This meeting has before it the consideration of the uses and abuses of endocrine therapy. We are, I think, discussing a science which is undeveloped, and we are attempting to discuss it as though it were fully matured. Let us suppose that this meeting is being held thirty years ago, and that the subject is the possibility of aerial flight. There would be a small band of enthusiasts who would insist that flight is much easier than air is a possibility, there would be a large band of destructive critics who would dismiss the matter as a fantastic absurdity. The parallel I leave to you, destructive criticism is not going to help us solve the problems of endocrinology, and though enthusiasms equally have their dangers, they tend to progress rather than the complacency of inaction.

Of the sections into which these papers are divided I am only prepared to say a little in regard to the parathyroid glands. I am quite prepared to admit that there is much empiricism connected with endocrine therapy; we rarely know the active substance we are dealing with, and still less do we know its mode of action. Yet with vitamins and light therapy we are as ignorant—even as with such homely compounds as the preparations of quill. It is generally stated that all endocrine glands secrete hormones or substances which accelerate or retard the velocity of biochemical reactions which are already in existence in living cells. Probably in the case of the thyroid gland this is true, possibly so in the case of the pancreas, the one may accelerate oxidative processes and the other retard it. But I am not at all sure that the hormone theory is applicable to all endocrine glands indiscriminately. I have recently obtained some evidence *in vitro* that the governing influence of the parathyroid glands upon the calcium content of the plasma may be due to the action of a substance in the nature of a protective colloid, the effect of which is to keep certain organic complexes of calcium and lecithin from precipitation. I have found that without parathyroid substance the calcium equilibrium of the solution I use occurs just below the tetany limit of 7 mg. calcium per cent. The addition of 2 mg. of parathyroid substance per 100 c.c. makes an appreciable difference, and raises the calcium

content. It is, however, impossible to go into the details of these experiments now. It is, I think, probable that a quantitative relationship may be found between the amount of parathyroid substance used and the calcium content of these experimental solutions. Such a result would explain why oral parathyroid therapy is usually a failure in tetany, while grafts or injected extracts may cure the condition. It is a question of the maintenance in the blood of a definite quantity of this protective substance. As Professor Vincent points out, it is interesting to note that Collip has found the oral administration of his concentrated extract is effective, while the ordinary dried gland is not effective.

I note that Professor Vincent has referred to the work of Dr. Scott on spinae, and has favoured it with an exclamation mark as though the results Scott claims pass all bounds of sane credulity. I would, however, point out four things: first, that calcium salts alone, either by injection or by mouth, have been tried by Scott without very much success; secondly, that Scott has obtained almost equally good results in spinae without calcium at all, using only the despoiled commercial parathyroid extracts; thirdly, that thyroid administration invariably causes a relapse, and fourthly, that a good many other people beside Scott, both at home and abroad, have had equally good results.

We are all fully aware that endocrine therapy has its uses, and equally that certain types of unscrupulous manufacturers may trade upon the ease with which purposely valueless preparations can be put upon the market at high prices. Yet is not this position common to all classes of saleable goods known, and is the puff advertisement peculiar only to endocrine products? There is, I think, a grave responsibility resting upon us as clinicians and laboratory workers, by observation and experiment we must endeavour to make these endocrine substances of greater value, if we can produce clear and definite evidence either of the action or of the preparation of these endocrine products, we shall not find, as Professor Vincent would seem to suggest, that the manufacturers of endocrine preparations are merely the capitalists of purposely useless "patent medicines."

Endocrine therapy has undoubtedly a big future before it, if we are not too eager to make it run before it can walk. Development may be slow, but, if considered effort is made, it must come. We may be quite certain, however, that development is not possible if we forsake the arena of the clinic and the laboratory, and rest upon the belief that investigation and confirmation of the work of others are valueless.

VI—F S LANGMEAD, M D, F R C P, Professor of Medicine St Mary's Hospital Medical School, University of London

PREVIOUS speakers have dealt so faithfully with the subject that there is not much left for me to say unless I draw upon the panegyrics of the vendors of endocrine products. Dr. Langdon Brown has spoken of the value of "trial and error" in clinical medicine as in the laboratory, but he will acknowledge, I am sure, that the trial must be a real one. We must know, on embarking on such a trial, more than appears on the label. At present, I am afraid, such trials, as far as endocrine products are concerned, are too often the employment of a substance of unknown constitution and variable strength, by a way by which it cannot act, for conditions which we fail to understand. For a trial to be valid the other components must be known. We cannot solve a problem where the components all equal the unknown quantity. I can do no more with the time at my disposal than touch upon the various extracts mentioned in the opening paper seriously.

Thyroid—Thyroid medication is little open to discussion. In cases where there is a lack of thyroid secretion its action is, of course, indubitable. In cretinism, for instance, I think its good effects are greater than some alienists (who see only the failures) would have us suppose. I have at present several cases of cretins whom I have watched from infancy, who have passed through puberty, and may now be regarded as normal, except that they are somewhat younger than their years. In so-called cretinoid children and those with here and there a possible cretin stigma my experience does not lead me to be so hopeful, nor have I seen much good effect in emmesis. There are two uses for

thyroid extract that is not mentioned in the opening paper—early rheumatoid arthritis and the enlarged thyroid of puberty. I am convinced that it is sometimes useful in both these conditions. I remember twenty years ago treating a case of rheumatoid arthritis with thyroid extract, and to my surprise the patient appeared to recover completely, since then I have met with many failures, but still with sufficient success to retain it in my armamentarium against this disorder. A point of interest, and one I think which points to a general rule in replacement hormone therapy, is the large quantities of thyroid extract which can be taken without result when the gland is not at fault.

Parathyroid—The only point I will make concerning parathyroid medication is this: if the calcium content of the blood is to be used as a gauge we must be sure of the accuracy of the findings. Dr A. C. Alport, working in the unit at St. Mary's Hospital, has shown, indubitably I think, that many of the figures regarding calcium content of the blood are quite erroneous, and that reliable estimations are very hard to come by.

Adrenaline—I have in passing a little criticism to make on intragastric administration of adrenaline. In the doses suggested its dilution in the stomach must be about 1 in 18,000, and in this strength, even in the stomach, it is hard to believe that it can stop gastrostasis when one remembers the difficulty sometimes encountered with 1 in 1,000 on a visible bleeding point.

Pituitary—I am not sure that one can separate out distinctly the functions of different lobes of the pituitary gland. Cases of so-called dyspituitarism form a mixed group, while fat children are too readily labelled dyspituitarism. Obesity with overgrowth and precocious sex development appear to be as common as or commoner than the original syndrome of Frohlich. Puberty, with or without thyroid or pituitary administration, often changes the picture completely. I can agree that extract of pituitary gland produces results by the mouth as judged by the blood sugar curves. In two cases worked out by Dr E. G. B. Calvert of the Medical Unit at St. Mary's Hospital, in which there was want of sex gland development, the blood sugar curve was made normal by the administration of posterior lobe extract, in another two without gonadal defect a similar result followed administration of extract of anterior lobe, in both the extract was taken by the oral route.

Gonadal—I have seen little effect from gonadal extract, as advertised, but by a special method of extraction from bull's testicles, on the lines of the preparation of insulin, Dr Calvert appears to have isolated a substance which had an effect in causing rapid loss of weight in a case of severe dyspituitarism with gross obesity and want of development of the testicles. The weight had previously remained unchanged by thyroid and combined thyroid and pituitary administration.

In conclusion, I would point out that Dr. Langdon Brown speaks of some six or seven ductless gland preparations only as being of value, yet the number on the market is more nearly sixty or seventy. This can only mean that a profitable market exists for a large number of extracts which are valueless. I think that clinicians, whether workers in laboratories or not, should welcome the cold douche which Professor Swale Vincent administers in his endeavour to stop such gross abuse of scientific investigation.

GENERAL DISCUSSION

Dr. Woods Hutchinson (U.S.A.) reminded the meeting of the widespread occurrence of endemic goitre in the United States of America, and of the striking results obtained by adding traces of iodine to the diet. Table salt was too pure, and in some places iodine was added to the salt prepared for table use. Elsewhere other measures, such as the addition of iodine to the drinking water, had had most beneficial results.

Sir James Berry (London) said that in this controversy he was wholeheartedly on the side of Professor Swale Vincent. From his clinical experience as a surgeon he thought that, with the important exception of the thyroid, there was very little, if any, therapeutic value in most of

the so-called "endocrine" preparations when administered by the mouth. He had grave doubts whether the parathyroid glands in themselves had really anything to do with the production of tetany, and whether any preparation made from parathyroids did anything for the alleviation of this condition. The thyroid, parathyroid, and thymic tissues were so intimately connected with each other in their anatomical relations that, as regards conclusions to be drawn from their functions, it was preferable to consider these organs together as one organic whole. The so-called parathyroid glands had no constant anatomical position, but might be found almost anywhere about the back of the thyroid, or even within the gland itself. He had examined over fifty parathyroids from animals whose parathyroids were used in the manufacture of commercial parathyroid preparations, and found that most of these "parathyroids" contained a considerable quantity of thymic tissue as well. Conclusions drawn by physiologists as to the functions of the parathyroids, based upon experiments upon animals, should be received with caution. A year or two ago, on the public invitation of the distinguished director of a well-known pathological institute, he had attended forty operations for the removal of parathyroids from rats, which experiments, he had been assured would afford him complete proof that removal of the parathyroids in rats certainly produced tetany. These experiments, although performed by a physiologist of great skill, were, in such small animals, necessarily somewhat crude. He could not help thinking that if he (the speaker) performed his operations upon the human thyroid in an analogous manner almost any complication, including tetany, might easily follow. The condition of the rats in the period following the operations bore but a faint resemblance to that of tetany in the human subject. His scepticism of the reality of the supposed "proof" was more than justified by what he had witnessed. In the human subject it was quite impossible to remove the whole or even much of the parathyroid tissue without seriously damaging the thyroid itself, and consequently interfering greatly with the function of the thyroid apparatus as a whole. He had himself removed a portion of the human (goitrous) thyroid gland more than fifteen hundred times, commonly for pressure symptoms, and knew that he had often removed a good deal of parathyroid tissue. Nevertheless, he had never yet seen or heard of tetany following any of his operations, although he had been in the habit of following up the results of his operations, and knew, in nearly all cases, what the condition of the patients had been for at least one year after the operations. He thought that the doctrine taught by some, that every portion of a thyroid lobe should be removed, even for exophthalmic goitre, was unwise. He also thought that bilateral operative intervention with the lumen of the thyroid was a most dangerous proceeding, and he never did this in any of his operations. He had seen a good many distressing cases of tetany that had followed operations by others, and thought that this complication was generally due to disregard of the above principles and possibly also to other reasons as well. A few post-mortem observations had been made on the pathological condition of the parathyroid glands in the idiopathic tetany that occurred in connexion with dilatation of the stomach or of the large intestine. These did not seem to support the view that disease of the parathyroids was the cause of these forms of tetany. He was glad to hear that Dr. Vines, if he had understood him rightly, was now prepared to admit that parathyroid preparations seemed to have little or no beneficial effect on tetany.

A term that was used much too loosely by many clinicians was "hyperthyroidism." It appeared to the speaker, judging by the number of patients that were sent to him by physicians or general practitioners with a ready-made diagnosis of "hyperthyroidism," that many enlarged thyroids, if accompanied by tachycardia, were too readily supposed to be in a condition of "hyperthyroidism." In many, indeed in most, of the common enlargements of the thyroid which constituted simple endemic goitre, the gland was certainly not overactive, but degenerated, and presumably less able to perform its normal functions, whatever these might be. Yet such goitres were often associated with tachycardia. He had frequently removed old fibrotic adenomata, cysts, and other tumours from the thyroid glands of

patients with tachycardia, often with much benefit as regards this condition. Yet these thyroid glands, although much enlarged, were certainly not hypertrophic. In many of such cases there was doubtless some ill understood dysthyroidism. This was a better term than "hyperthyroidism," which implied a theory that was, as yet, by no means proved.

Clinically there were many cases of tachycardia in which the patient also had a goitre. But the goitre was not necessarily the cause of the tachycardia. Also there were many cases in which the tachycardia was apparently caused by the goitre, and in which nevertheless there was no pathological evidence that the thyroid was overactive. He had, although rarely, seen cases in which so much of the gland had been removed by operation, or by disease, that the patients were obviously suffering from loss of thyroid function (true hypothyroidism), and yet at the same time these patients continued to have the tachycardia of so-called "hyperthyroidism." It was very difficult to explain such cases except on the assumption that the tachycardia was caused by some form of dysthyroidism rather than by hyperthyroidism. He would venture to urge upon physicians and general practitioners the importance of a more careful study of the morbid anatomy of goitre. Abundant opportunities for study were afforded by our museums and, now and then, by operating theatres as well. In reference to a remark by a previous speaker about the "new" discovery of the value of iodine as a cure for goitre, Sir James Bell characterized the recent theory that endemic goitre was due to "lack of iodine" as absurd and contrary to the observed facts of the distribution of this disease. Anyone who would take the trouble to investigate endemic goitre "in the field" (to borrow a geological term), and especially in many different parts of the world, would quickly be convinced that whatever the essential cause of endemic goitre was, it was not due to "lack" of anything, but to something present in the drinking water. What that something was, whether organic or inorganic, had not yet been satisfactorily proved. It was quite certain that the purer drinking water was, the less likely it was to produce goitre. That iodine was an excellent remedy for certain forms of goitre, especially for the softer and earlier forms, had been known for centuries. The speaker himself had used it for such cases for many years, as had doubtless many of those among his audience. To say that because iodine was a good remedy for many forms of goitre, therefore these forms were caused by a "lack of iodine," was, to say the least, illogical. It would be but little more absurd to say that because quinine was a good remedy for the enlarged spleen caused by malaria, therefore enlargement of the spleen was caused by a lack of quinine. Although it was quite true that endemic goitre was far more common in mountainous regions than at the sea coast, it was quite incorrect to assert that goitre did not occur as an endemic disease in any seaside districts. A great deal of what he could only term ridiculous nonsense had been appearing of late in the lay papers, and not a little, he was sorry to say, in medical papers, on the subject of the causation of endemic goitre by lack of iodine and even lack of vitamins! Much of this literature came from the pens of those who had seldom or never seen the inside of a goitre, or taken any trouble to study it in the field.

Dr L. J. PICTON (Holmes Chapel) said it had been mentioned by Dr Woods Hutchinson that in the United States table salt was prepared with a trace of iodine and was used there in some districts as a prophylactic against goitre. Iodized table salt was also prepared in the salt reworking works of Winsford in Cheshire. Dr Langdon Brown in his paper had not referred to the great influence of the thyroid upon the liver, but in his book on the principles of physiology applied to medicine he had done so, and had indicated its use in jaundice. Dr Picton had been impressed, in practice, by the relief afforded by the administration of thyroid extract in the itching and malaise that often accompanied jaundice. The association of thyroid function and hepatic disorders had been discovered by the observation that ligation of the common bile duct in a dog was followed by swelling of the thyroid. Conversely he had observed that a dog suffering severely with symptoms of obstructive jaundice was rapidly relieved by the administration of thyroid extract. The association of

the activities of the liver and thyroid seemed to him to be pregnant with interest.

Professor J. A. NIXON (Bristol) asked who demanded the various products on the market. He thought that among the large audience present there must be some who used them and would be willing to give their results.

Dr LANGDON BROWN and Professor SWALE VINCENT replied briefly to the discussion.

LANTERN DEMONSTRATION

INTESTINAL DIVERTICULA

Dr E. I. SARGENT said that diverticula of the intestine were frequently found. He had seen over 200 cases. In 1,000 consecutive examinations of the alimentary tract at Ruthin Castle (Duff House) diverticula were noted by his radiological colleague, Mr. Marver, in 145 patients—that is, 14.5 per cent., in 38 there were duodenal pouches, jejunal in 6, ileal in 7, appendical in 6, and multiple diverticula of the colon in 100—that is, precisely 10 per cent. When jejunal pouches were seen they were generally associated with duodenal ones. [Each point was illustrated by lantern slides.]

He had formerly proposed the term "diverticulosis" for the condition described, reserving the term "diverticulitis" for the later stage in which inflammation, involving surrounding structures, and particularly the peritoneum, occurred in and around diverticula.

DUODENAL DIVERTICULA

The development of these in middle age had been watched in some of the patients over four to seven years. In a number of cases the pouches appeared to do no harm, but there was often great delay in them, varying with the width and position of the mouth, and in a considerable proportion symptoms attributable to the diverticula were present. Thus in 18 out of 38 patients with duodenal pouches symptoms were, after careful investigation, ascribed to irritation from the pouch or pouches, in 10 others the relation of the complaint to the pouch was indefinite and in the remaining 10 there were no attributable symptoms. The symptoms simulated roughly those of duodenal ulcer: flatulence, fullness or discomfort at some time after food, pain, vomiting, or diarrhoea might be complained of. The symptoms were amenable to treatment in 13 out of the 18, consisting of (1) instructing the patient to lie for half an hour about three hours after food, in the position which had been shown on the x-ray table to aid best the emptying of the pouch, (2) lubrication of the pouch by paraffin, (3) disinfection by such an antiseptic as boric acid, (4) calomel, plain food, and general treatment. In one case, of multiple duodenal and jejunal pouches, gastro-enterostomy had been successful. In two others excision or irrigation of the pouch seemed desirable, but advanced age and other infirmities were against it.

MULTIPLE COECIC DIVERTICULOSIS

The speaker then described a prediverticular state of colon diverticulosis. This had been discovered by O. A. Marver and was first mentioned in 1923 in Volume I of the *Duff House Papers*. Radiograms were thrown on the screen. The prediverticular state appeared in patches in the large intestine: these showed a ragged outline of the bowel with partial contraction, which did not dilate in any position. It had been observed in 20 out of the 100 cases of colic diverticula, and, in 16 of these, incipient or established diverticula were seen in or near the affected area. It was best shown with the butter-milk and barium meal or enemata. With cereal mixtures the same area might show inhibition. The patches were often small but sometimes the whole circumference was involved giving an appearance of constipation. Over 10 inches of bowel had been seen in this state. The muscular wall was irritated and contracted, but there was no evidence of obstruction. It was at this stage that the mucus herniae began to be pushed through the wall. The prediverticular area might be tender.

This new observation altered the conception of the disease, the formation of herniae being preceded by inflammatory and not purely mechanical causes.

An infective origin was suspected and was supported by the findings that haemolytic streptococci in the faeces were

1032 DEC 5, 1925]

MEMORANDA

more often present in patients with diverticulosis, and especially with the pyoderma state, than in others. Strong support was also given to the infective view by the observation that diverticulosis was very frequently associated with spondylitis deformans and with infected teeth. To test this the records of 100 control patients were examined, of the same age (58) and sex (71 males and 29 females) as the 100 diverticular patients. In the controls 20 per cent had radiological evidence of spondylitis, in the diverticular 72 per cent. The figures for abscesses at the roots of the teeth were 38 per cent and 65 per cent respectively. It was suggested, therefore, that multiple diverticulosis of the colon was a disease of infective and inflammatory origin, its first stage being the pyoderma state. The second stage, of formed diverticula, might be quiescent for years, but was not infrequently associated with symptoms such as constipation, flatulence, discomfort, pain, or diarrhoea. These symptoms in nearly all cases were amenable to treatment, comprising especially the use of purgatives, intestinal lavage given at low pressure, and removal of other sources of infection such as diseased teeth. The third stage of diverticulitis, with peritoneal involvement, well described by Telling and Guener in 1917 in the *British Journal of Surgery*, was relatively uncommon. In its definite form it occurred in 5 only of the 100 patients with multiple diverticulosis of the colon.

Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

QUININE AMAUROSIS

The infrequency of the occurrence of quinine amblyopia is the excuse for publishing this note.

A ship's steward presented himself at St Paul's Eye Hospital, Liverpool on September 3rd 1924 complaining of defective vision. It was elicited that up to August 1924, his sight had been very good. One night in August, while off the West Coast of Africa, he did not feel very well and swallowed 30 grains of quinine sulphate in tablet form as he had been accustomed to do. He had had malaria on four occasions and had been accustomed for years to take prophylactic doses of quinine (5 grains) frequently. On waking up on the morning following the dose of 30 grains he discovered that he was deaf and had lost all perception of light. Five days elapsed before his hearing improved or perception of light returned.

The examination at St Paul's on September 3rd 1924, revealed the following conditions. Vision in each eye was 6/36. Not improved with glasses. The refraction was emmetropic. The pupils were equal but rather dilated and sluggish in their reaction to light and accommodation. There was a central scotoma to red and green. The fields of vision were contracted down to the 100 line. The discs were intensely white and all the retinal arteries markedly constricted. The patient was admitted to hospital and treated with strychnine purgatives etc.

The discs were intensely white and all the retinal arteries markedly constricted. The patient was admitted to hospital and treated with strychnine purgatives etc. On September 11th the vision had improved to R.V. 6/12. The central scotoma to red and green had disappeared. The visual fields remained as before. The edges of the discs were now beginning to show slight atrophic cupping. The retinal vessels were still constricted.

The condition now (over twelve months) shows no change from the examination on September 11th, 1924.

ERYSIPELAS TREATED BY FOREIGN BLOOD INJECTION

The following case of successful treatment of severe erysipelas of the face in a baby, aged 12 months, by intramuscular injections of the father's blood seems to be worthy of publication.

On October 11th I was called to see a male baby. Two days previously two nodular swellings had been discovered under the left ear. Hot fomentations were applied and a rash appeared the next day. This rash extended and on October 10th the child had become seriously ill. By the next day it was clearly a case of erysipelas of the left ear. The rash involving also the eye and the scalp. The rectal temperature was 105° there was sickness and the child looked very ill. The local application of combined ichthylol ointment was associated with the oral administration of the tincture of iron perchloride. By the next day the rash had spread further over the scalp, and the upper lid of the

left eye became involved. The child was very drowsy and the rash assumed the type of erysipelas bullosa. Albumin was found in the urine. To relieve the severe headache and an ice bag to the head were advised. On the morning of October 11th I withdrew 15 ccm of blood from a vein of the father who was young and strong, and injected it into the buttocks of the baby. There was no need to dilute the blood as there was no delay in injecting it. The rash had now spread to the forehead to the right eye, and covered most of the scalp. The same evening the rectal temperature fell to 102°, but on the following day both eyes were closed by the swelling of the lids, and only the occipital part of the scalp had escaped. The rectal temperature was 105°. A further 20 ccm of the father's blood was injected in the evening the temperature fell to 104°. On October 16th it was 102°, the bullae were disappearing, and the child could open the left eye. The rash had apparently ceased to spread and the lower part of the face the neck and the occipital part of the scalp were not involved. A further injection of 20 ccm of the father's blood was given and in the evening the temperature was 99°. From that time the rash diminished steadily, and it disappeared completely in two or three days, the child making a quick and uninterrupted recovery. On October 21st there was a mild urticarial rash all over the body, but the rectal temperature was 98.5°.

The technique I employed was very simple with the ordinary aseptic precautions I withdrew the blood from the cephalic vein of the father in a room adjoining the sick-room, and immediately injected it with a fresh needle into the child's buttock, the blood having no time to clot. I thought that an intravenous injection of the blood would be rather risky in a baby with erysipelas, and would, moreover, have necessitated preliminary tests of the suitability of the blood of the donor. I chose, therefore, the intramuscular route as the safest. In cases of erysipelas in adults I would suggest a dose of 40 to 60 ccm of fresh human blood. I think the curative effect of the blood transfusion in this case depended upon the combined action of parenteral protein injections and the general antitoxins of the normal blood—"para specific" action.

AN EARLY SYMPTOM OF PREGNANCY

I draw attention to a very early and constant symptom of gestation which, so far as I am aware, is not mentioned in any of the standard textbooks on obstetrics.

In almost every case of pregnancy, as early as the first week after the first intermitted monthly period, it can be elicited from the patient on inquiry that the labia majora feel tense and swollen, especially when she walks or sits down on a firm seat, the sensation of fullness being accompanied by occasional dull aching pains in the labia. This phenomenon is doubtless due to the venous congestion of the parts, to which also are due the cyanotic colour of the macron membranes of the vulva and vagina, and the venous arborizations on the inner surfaces of the thighs—both well known early signs of pregnancy. These signs are, however, often obscure or wanting, particularly in brunettes and in dark skinned races, whereas the subjective feeling of tension and swelling in the labia is in all cases constant and unequal.

The symptom described persists until about the end of the third month, when the uterus ceases to be a purely pelvic organ and rises into the abdomen.

MALARIAL TREATMENT OF TABES DORSALIS

Tabes dorsalis and general paralysis of the insane are so closely related, the two diseases being frequently found in the same patient, that a method of treatment which has given quite good results in the latter disease seemed worth trying in the former. Unfortunately, the case now recorded had not been diagnosed till it was too far developed, and once degeneration has occurred it is not possible for nervous tissue to be restored, so that we could only hope that the disease might be arrested. This point was carefully explained to the patient.

Although tabes dorsalis shortens life very little, it is, to say the least, a great disability, and optic atrophy may well be called a catastrophe, the result of treatment in this case should encourage others to try this method in the earlier stages of the disease before these symptoms have developed.

The patient is a single man, aged 30 who gave no history of syphilitic infection but had suffered from septic ulcers of the legs in 1915. Severe pruritis in the legs commenced in 1916. When examined in September, 1924

pruritis causing sleepless nights. In November, 1924 he had severe neuritis of the legs and a moderate amount of ataxia. The right pupil was larger than the left. Both pupils reacted to accommodation but very slightly. Light Rombergism was marked, the knee-jerks and Achilles tendon reflex were absent. The Wassermann reaction of the blood was positive. In March 1925 after three courses of silver salvarsan and a short course of bismuth there was very little change in the clinical condition. The Wassermann reaction in the blood showed a 'trace of fixation' in the cerebro spinal fluid it was positive. On April 25th the patient was inoculated with benign tertian malaria intravenously and the temperature went up on April 29th. The rises of temperature were of very moderate amount for the first two weeks (mostly 100° to 101°), but on May 13th 104° was registered. The patient was allowed to have twelve rigors they occurred regularly on alternate days and the temperature reached 104° or over on nine occasions, quinine sulphate (30 grains) in solution was then given daily for three days. This sufficed to cure the malaria. In July a course of silver salvarsan was administered in amount on June 30th 1925. Ataxia improvement moderate. Pupil light but definite. Rombergism marked improvement. Deep tendon reflexes no change. Lightning pains marked improvement. Weight 3 lb. Sleeps well. Appetite good. Increase. Cerebro spinal fluid Wassermann, negative. Cell count normal. Excess of globulin sugar normal.

CLINICAL AND SCIENTIFIC PROCEEDINGS

WEST BROMWICH DIVISION

Surgery in General Practice
A MEETING of the West Bromwich Division of the British Medical Association was held on October 6th, when Mr. R. T. Rose, assistant surgeon to the Birmingham General Hospital, read a paper on surgery in general practice.

Mr. Rose gave an account of various associated surgical conditions approaching them chiefly from the practical standpoint of diagnosis and treatment.

Tonsils and Adenoids.—The tonsils were not effete organs, but protected against infection especially in the young. It was probable that they were too often sacrificed unnecessarily, many cases of mild degrees of sepsis or hypertrophy that could have responded to conservative treatment being operated upon. There were two indications for operative treatment: gross hypertrophy which was injurious by mechanical obstruction and interference with breathing and the development of the child, and, secondly, deeply buried tonsils, though often quite small and great tonsillar glands and were also liable to damage the lymph glands into which they drained. Glands so damaged were especially liable to invasion by the tubercle bacillus. Cervical adenitis doubtless sometimes tuberculous, so damaged were usually in general practice, and was satisfactory in most cases and removed the glands completely with their capsules. Shaving of the glands by a sharp guillotine was worse than useless, since it left a raw area to become infected. Small, buried tonsils required dissection because they were usually adherent from peritonsillar inflammation. All tonsils in patients over the age of 10 years were best dissected out rather than removed by the guillotine. Tonsillectomy was regarded too lightly by the public the anaesthetic and haemorrhage risks were high.

Treatment of Haemorrhoids by Injection.—This was a very old method recently brought to the fore again, the technique was simple and the results encouraging. The method was admirably suited to general practice and depended for its success on the production of fibrosis in the pile by the injection into it of an irritant fluid. The method was painless if properly performed, and it could be used in cases in which an operation was inadvisable on account of age or physical infirmity. Careful selection of cases was essential, and any complication rendered the case unsuitable for the method.

Blood transfusion was useful in secondary anaemias, pernicious anaemia, septicaemia and other blood diseases besides severe post-operative haemorrhage. It might be used more widely in practice. The danger of giving an incompatible blood must be noted, and the easy method of testing the serum

of the patient directly against the blood of the prospective donor afforded a rapid means of selecting a suitable donor. The citrate method of transfusion is easy, it required only simple apparatus, and appeared to be almost as efficient as whole blood transfusion.

The 'acute abdomen' was an ever present problem in general practice, acute appendicitis perforated peptic ulcer and intestinal obstruction—the three commonest conditions—were briefly considered.

Acute appendicitis was easy to diagnose when the classical signs and symptoms were present, difficulty arose when the appendix was abnormally situated in the pelvis beneath the liver, or retrocaecally. Pelvic appendicitis was especially liable to be confused with tubal conditions. The symptoms were always less pronounced than when the inflamed organ was in the abdomen because it was not related to the muscular abdominal wall, and hence came the absence or lessened degree of abdominal rigidity. Further, the absorptive powers of the pelvic peritoneum were less than the abdominal and therefore the constitutional symptoms were less marked. The condition was, as a result, often advanced before the diagnosis was made. The chief evidences were some degree of lower abdominal pain, with mild pyrexia and general symptoms, on examination there was a varying degree of tenderness and slight rigidity in the lower abdomen. A rectal examination should always be made and would reveal tenderness and slight rigidity swelling to the right of the rectum or in Douglas's pouch. A distinction from tubal conditions was always difficult, but a shrewd guess could usually be made. In tubal disease menstruation had always been irregular and variable in amount and painful, while a certain degree of vaginal discharge was common. On abdominal palpation both iliac fossae were tender and the rigidity was slight. It was possible as a rule to make out per vaginam that both tubes were enlarged or tender, for it was uncommon for only one tube to be affected. The differential diagnosis was important, for it was best in most cases to operate on tubal inflammations in the quiescent condition. The subhepatic appendix appeared to occur in about 15 per cent of cases. In adults it was liable to be confused with acute cholecystitis, which was of little moment, since both conditions required operative treatment. In children confusion with a right-sided pleuropneumonia might occur which was a serious error. In right-sided basal pleuropneumonia referred right-sided abdominal pain and rigidity might be present. The chief difference lay in the greatly increased respiration rate in pneumonia and the respiratory distress. The illness also commenced not infrequently with a rigor and the temperature was higher than in appendicitis. It had to be admitted that little reliance could be placed on the temperature in appendicitis since some of the worst cases of gangrene might be afebrile. The pulse was the best danger signal. In early stages it was rare to get signs in the chest, the first to appear was the friction rub. Should any doubt exist as to the diagnosis a few hours delay would clear matters up. Retrocaecal appendicitis was most often confused with renal conditions especially acute pyelitis in children and renal colic in adults. A careful examination of the centrifugized urinary deposit should prevent error, as blood cells or pus and organisms would be found.

Perforated Gastric or Duodenal Ulcer.—The chief danger of overlooking this condition lay in the fact that the practitioner might be called in when the patient was in the period of recovery after the shock of a small perforation was over. The history and the continued rigidity, with a rising pulse rate, should sound the warning note.

Acute Intestinal Obstruction.—When the obstruction was low down the condition was usually obvious. Difficulty occurred in cases of high obstruction where there was no distension of the abdomen and the vomit never became truly faeculent. More over the bowel below the obstruction might respond once or twice to enemata before it was quite empty. Such cases of high obstruction occurred most frequently in young adults and were the result of tuberculous adhesions. Repeated attacks of intestinal colic associated with intractable vomiting, called for laparotomy.

The chronic abdomen was less well recognized as a clinical entity than the acute abdomen but it was very common and important. The condition was most frequent in the female sex. A single woman or else one who had had repeated pregnancies. She was usually sallow of complexion and grapt of frame with many symptoms: constipation, flatulence, dyspepsia, nerves, and gastritis figuring prominently. By physical examination two types could be distinguished: the virginal type, with a long narrow scaphoid abdomen and the maternal type, with a sagging flabby paunch. The kidneys were mobile and easily palpable, the stomach low and splashy and the caecum voluminous distended with flatus that gurgled freely under the finger. This last condition caused some discomfort and local tenderness, and often a scar revealed the fact that a diagnosis of

chronic appendicitis had been made and acted upon. In old standing cases scars might show that such operations as nephropexy and hysteropexy had been performed, often with temporary but never with permanent relief. The malady was as much mental as physical, physically there was a varying degree of visceroptosis and atonicity of the organs, and mentally a morbid introspection and self analysis which exaggerated and distorted the slightest ache or pain. Treatment was difficult and often unsatisfactory. Daily cases might respond to a careful fattening cure, together with an efficient abdominal support, abdominal massage, and suitable mild aperients. But question of operation could inevitably arise in most cases, but no operation should be undertaken except after prolonged investigation and observation. It should then take the form of a thorough investigation of the whole of the abdominal viscera through an adequate incision. Fixation operations on the colon, stomach, or kidneys were of little value and seldom required. A thorough exploration should help to put the mind of the patient at rest, as it eliminated the possibility of any organic lesion being overlooked. The mental state of a patient was the difficult problem, and all efforts must be made to divert her mind from her condition.

Early Diagnosis of Malignant Disease.—Two reasons existed for the late stage at which cancer patients came for treatment until advanced, the late always associated cancer with pain. Any lump in the breast of a patient over 40 years of age should be regarded as cancer until definitely proved to be otherwise. The factors upon which they were chiefly dependent for a positive diagnosis were the hardness of the tumour, fixation to skin or pectoral fascia, and the extent of the glandular enlargement. If any of these were present there could be little doubt, but in early cancer, in the stage when it should be their aim to recognize it, none of these were present. Chronic interstitial mastitis of the lobular type involving only a portion of the breast was the most difficult condition to distinguish from early cancer. Here a wedge shaped sector of the organ was diffusely thickened and lumpy rather than presenting a definite tumour, though sometimes a tense cyst stood out as a firm elastic swelling in the inflamed gland tissue. The glands might be slightly enlarged, the nipple was not retracted, and there was no skin fixation. In such a case the diagnosis of mastitis was easy, especially if the opposite breast was involved, but many cases were not so clear cut as this, and the diagnosis of malignancy or otherwise could only be made on a balance of probabilities. Exploration of these doubtful tumours should be insisted upon. If at the operation the naked eye appearance suggested malignancy, then there was some doubt as to the procedure. Even when there was some doubt as to the question of malignancy on naked eye examination, for though every radical operation should still be performed, for though every severe procedure, this occasional error would be more than counterbalanced. Exploration with removal of a piece for section was liable to disseminate the infection, but it was sometimes necessary in cases where naked eye examination should be growth was indecisive. In such cases the radical operation, widely removed locally at the time, and the radical operation proceeded with as soon as possible afterwards. All breasts which were the seat of severe mastitis should be locally removed, since carcinoma followed in an appreciable percentage of cases. Cancer of the rectum was a form of cancer which generally came at the most hopeless stage to the surgeon. This was due to the fact that, apart from haemorrhage, which was always attributed to piles, the early symptoms were so slight that even an intelligent patient rarely regarded them seriously. Every patient complaining of rectal or colonic symptoms should be examined digitally with the proctoscope, and, if there was the slightest doubt, with the sigmoidoscope as well. Piles were the only conception of rectal disease and on examining patients complaining of piles all forms of rectal disease were encountered. Unfortunately it was still common to meet with laxity in the examination of rectal cases than the preceding stomach was even more difficult of diagnosis than the stomach. Any patient, especially after the age of 40, who developed a slight but persistent dyspepsia was open to grave suspicion, particularly when this was associated with slight loss of weight and failure of appetite. The dyspepsia associated with gastric and duodenal ulcers, with gall stones, and with appendicitis were periodic and not persistent, at any rate in the early stages of the diseases. Radiograph, and test meals were of great value in the early stages, but when a palpable tumour was present the case had nearly always passed beyond the limits of operation. No definite means of making a diagnosis existed in the early stages, and operation should often be advised on suspicion after a careful weighing up of the case, even if this had to be done in the face of negative x-ray and biochemical findings. When a diagnosis of carcinoma of the stomach could be made with certainty it was usually beyond surgical relief.

Reports of Societies.

INSANITY AND CRIME

At a meeting of the Royal Medico Psychological Association, held in the rooms of the Medical Society of London on November 17th, with the President, Sir FREDERICK MORR, KBE, in the chair, sympathetic reference was made by the President and Dr R. H. COLE to the death of Dr Percival Langdon-Down, and to his long continued work in connexion with mental deficiency.

Dr JOHN CARSWELL read a paper entitled "Insanity and crime: some suggestions arising out of the Athin report." He said it could be taken that, at least in form, the M'Naghten rules had received such fresh support as to preserve them in being for another generation. Yet the medical profession would not admit that the controversy was ended, indeed, there seemed a desire for adjustment of the medical and legal points of view. The rule recommended by the Athin Committee read "It should be recognized that a person charged criminally with an offence is irresponsible for his act when the act is committed under an impulse which the person was by mental disease in substance deprived of the power to resist." The Committee added, "It may require legislation to bring this rule into effect," and, later, "We have no doubt that if this matter were settled most of the criticisms from the medical point of view would disappear." Dr Carswell said that members of that association would acquit themselves, as medical men acquainted with the clinical aspects of disorders of mind, of expressing their ideas as to what they might regard as the test of criminal irresponsibility in these terms, which were lawyers' terms, and, indeed, all the trouble had arisen in that way. Did the accused know what he was doing? And if he knew, did he know that it was wrong? These were the formulae framed by lawyers, and the psychiatrist had no responsibility for them. Fitzjames Stephen, in his *History of the Criminal Law* (vol. II, p. 174), after considering Maudsley's observations, said "I understand by the power of self-control the power of attending to general principles of conduct and distant motives and of comparing them calmly and steadily with immediate motives. Diseases of the brain and the nervous system may cause definite intellectual error and if they do so their legal effect is that of the innocent mistakes of fact. Far more frequently they affect the will by either destroying altogether or weakening to a greater or less extent, the power of steady, calm attention to any train of thought."

Dr Carswell went on to say that a series of cases in recent years were available to show that judges had charged juries in the sense indicated, and even in the much debated Ronald Truoc case Mr Justice McCarty left three questions to the jury, two first two were in the terms of the M'Naghten rules, and the last was expressed in the following terms:

Even if the prisoner knew the physical nature of the act and that it was morally wrong and punishable by law, yet was he through mental disease deprived of the power of controlling his actions at the same time? If yes then in my view of the law the verdict should be Guilty but inane.

The point Dr Carswell wished to make was that all the judges who delivered charges in the sense he had quoted agreed that uncontrollable impulse could be read into the M'Naghten rules—that was to say, the rules were logically insufficient unless some such idea could be incorporated with them. The recommendation was not based upon any unproved or doubtful category of mental disorder, nor upon any principle of criminal responsibility not already recognized. His object in this communication had been to start a fresh discussion of the problem of insanity and crime from what he understood to be the point of view of the Athin Committee, with the hope of reaching some points at which medical men could agree that the legal conception of responsibility of the insane was more in accordance with the clinical facts as the case known to psychiatrists than at present was the case. Dr BARKER SMITH said people were responsible in various degrees for what they did, and that was largely proportional to their education and culture. Many men acted with the same quick unreflective impulse as lower animals. This question of responsibility in a particular

person was a question for the medical man, not for the lawyers.

Sir BRUCE DOUGLAS said Dr Carswell seemed to think that the conception of irresistible impulse was implicit in the M'Naghten rules, a very strong statement to make in his, the speaker's, view, and he did not see that any practical result could arise on this idea.

Dr G. HENDERSON said that in medico-legal cases the question of responsibility constantly came up, and if this question of "irresistible impulse" (a term never yet properly defined) was likely to be brought into them, the issue would be more complicated than at present. Another important kind of case was that in which a prisoner's state of mind was questioned, and the man sent to a criminal asylum without having been tried—in other words, without the question having been decided whether he was guilty or not. He suggested it would be well to try cases in which there was a certain amount of doubt as to the facts of commission.

Dr G. D. McRAE said a very important question arising out of this discussion was, "Is an insane man a criminal, whatever he does?" To him, it was cruel to say that a man ruling mentally was guilty for anything he did, and he regarded the expression "criminal lunatic" as archaic. An individual should be tried to prove whether he committed the act, or not. If he did commit the act but was found to be insane, the verdict should be "Proven but insane," for "guilty" in this relation was out of place. The question of responsibility should be left to the legal people. It had been said that medical superintendents of mental hospitals acknowledged the principle of partial responsibility by placing patients on parole, but the actual fact was that until the patient was certified cured the responsibility for him while out on parole attached still to the medical superintendent.

Dr T. B. HAZEL said that until the medical profession awakened to the fact that in these cases it gave evidence on a question which was not at issue—namely, that of insanity—and the judge charged the jury on the question of responsibility, they would always be playing at cross-purposes, and working under that absurd M'Naghten rule, which had caused grave injustice. Medical witnesses should see to it that they were examined and cross-examined on the real question at issue in the case.

Dr W. C. STALLAN (Broomfield) said the M'Naghten rules were really founded on a contradictory and unjustifiable view of the jury. The rules assumed a degree of stupidity on the part of the jury which required that they should be instructed by the judge, and there was the further requirement that the medical evidence should be filtered through the strainer of the M'Naghten rules. The doctor giving evidence had no opportunity of expressing his views in full and in clinical terms, because the assumption was that the jury could not understand them. Yet that same jury were supposed to be gifted to the much greater degree required to distinguish between an irresistible act and one which was unresisted. The present state of things resulted from excluding the jury from having a fair issue placed before them, hence the question was placed in the hands of the judge. It must always be borne in mind that there were very few murderers in whom something abnormal could not be found, and that abnormality could be magnified by medical witnesses to produce a verdict of "Guilty but insane", but if the matter were left to the jury they would form their own opinion of the facts and on the history and the various episodes brought out.

Dr J. M. MACKENZIE asked whether irresistible impulse was supposed to operate in persons who were sane as well as the insane. If so, where could the line of demarcation be drawn? Much might be learned on that from the late Dr W. H. R. Rivers's book *Instinct and the Unconscious*.

Mr DONALD CARSWELL spoke from the legal standpoint. He agreed that some of the hard things which had been said about the M'Naghten rules were justified, but asked how medical men proposed to get rid of them, as they were operative. He therefore advocated attempts being made to arrive at a concordant with the legal profession on the matter. He knew at least three senses in which the phrase "irresistible impulse" was used by lawyers.

Dr J. G. SOUTAR remarked that even after all this argument he had never yet seen a case in which he could say that irresistible impulse was the only evidence of mental disorder in a person. When such a plea was advanced investigation showed that a definite idea had preceded the particular act, perhaps for a long time. Impulsive acts were known to occur in perfectly sane people, and in them it was well known that the acts did not indicate insanity. If the M'Naghten rules could be wiped out members of that association would be in a much better position as medical witnesses. The medical man had to testify to the facts, and leave it to the judge and jury to say whether the facts testified to by skilled observers were indicative of that degree of unsoundness of mind which rendered a person irresponsible for his acts.

Dr PERCY SMITH said the association had done its best to show that the M'Naghten rules should be done away with, and that every case should be tried on its merits, with the fullest possible evidence. But the profession had been saddled with the rules by the verdict of the Court of Appeal in the True case, when Lord Birkenhead said they were the law of the land.

Dr CARSWELL, in a brief reply, said he recognized that the association had remained steadfast to its attitude, that the business of the medical man was to testify to the state of mind of the accused. That was the only logically sound position.

NEPHRITIS

At a meeting of the Section of Medicine of the Royal Society of Medicine held on November 24th, with the President, Dr HUGH THURSFIELD, in the chair, a discussion was held on the clinical aspects, treatment, and prognosis of nephritis.

Professor HUGH MACLEOD, in opening, said that there was really nothing new to bring forward except a few small points which required emphasis. From the clinical aspect nephritis was best divided into acute and chronic types, and all the chronic forms tended eventually to present the same picture. In the acute form all the renal functions were, temporarily at any rate, "knocked out," while in the chronic forms, the chronic interstitial nephritis of the textbooks, it was the elimination of the nitrogenous substances which was principally disturbed. He emphasized that there was no such disease as "chronic parenchymatous nephritis", this was really a subacute stage, and in the course of time patients suffering from this either got better, died, or passed into the chronic interstitial type, and this was confirmed by histological evidence. In the typical subacute stage waterlogging was the most striking clinical feature, and as far as the nitrogenous waste products were concerned the kidney was found to be doing its work well. It was a curious fact that as soon as chronic interstitial changes commenced the kidney again assumed its work of water excretion in a satisfactory manner and all oedema disappeared. With regard to the various tests for the diagnosis of nephritis, Professor Macleod urged that the simple tests gave all the information necessary and elaborate experiments were quite superfluous. Blood urea determinations and estimations of the concentration of urea in the urine were the two most satisfactory procedures. For the general practitioner the second of these was the more useful in ordinary circumstances, and this test was particularly important when it was realized that high blood urea figures might be found in conditions which were not strictly renal in origin. The presence and amount of albumin in the urine merely indicated the possibility of nephritis and gave no help as to the severity of the disease nor as to its prognosis. A simple estimation of the concentration of urea in any specimen of urine gave quite enough information, and if this was found to be between say, 25 and 3 per cent, any serious damage to the kidney could be excluded. As far as treatment was concerned, Professor Macleod stated that there was nothing new to discuss. He thought it rather absurd to give large amounts of salt to cases of acute nephritis if the object was to reduce the amount of protein in the diet, but recent work had shown that protein in moderate amounts was not harmful to the kidney. Giving excess of water to wash out the kidneys was a useless

procedure With regard to the treatment of oedema in the subacute cases, physical means were probably more useful than drugs, but large doses of urea were often helpful, and recent work in America went to show that calcium chloride and ammonium chloride might sometimes be successful For prognosis the estimations of blood urea and urea concentration in the urine give most help In cases of hyperpiesis the outlook largely depended on whether the kidneys were affected or not, and, generally speaking, the longer obvious kidney damage was delayed the better the prognosis

Dr W LANGDON BROWN expressed his complete agreement with Professor Macleay, and welcomed particularly the indicated release from the tyranny of tests He recalled that he had opened a discussion on a similar subject fifteen years ago, and had then stated that the conventional views with regard to restricted protein intake, a knowledge of the total urea output, flushing out the kidneys, and elimination of metabolic products by the skin were all based upon erroneous ideas Modern work had confirmed these views In acute cases he believed in giving fruit juice and sugar for the first few days, and in subacute cases he thought urea more useful in getting rid of oedema than a high protein diet He thought diaphoresis was very useful as long as the patient was not exhausted by it, and referred to the treatment of one case of uraemia by hydrochloric acid With regard to nephritis in general, Dr Langdon Brown thought that the patient's lot would be greatly improved when it was more widely recognized that many of the routine procedures adopted were futile

Dr LEWIS SMITH agreed as to the usefulness of the simple chemical tests, but pointed out that the kidney was not the same as a test tube, and there were many things about kidney disease which were not understood It was possible that the kidney possessed an internal secretion fifteen years ago he had treated oedema of renal origin in children with kidney sandwiches

Dr A BOUSFIELD said that in general practice acute nephritis was very rare, and pyelitis and cystitis were much commoner causes of albuminuria He thought the treatment of nephritis was largely preventive

Dr R S ALLISON described certain modifications in the urea concentration test used at Ruthin Castle The modifications, which had been found very satisfactory, were those proposed by Calvert in the BRITISH MEDICAL JOURNAL of January 10th, 1925 (p 64) He inquired as to the prognosis in the haemorrhagic type of nephritis in children The PRESIDENT answered this question, and said that in his experience in children the type of nephritis with massive haematuria completely cleared up

Professor MACLEAY said that his experience in adults was the same with regard to these haemorrhagic cases He replied briefly to several of the points raised by other speakers

PYLORIC STENOSIS IN INFANTS

At a pathological meeting of the Liverpool Medical Institution on November 19th Mr W A THOMPSON read a paper on pyloric stenosis in infants

Mr Thompson summarized the various opinions about the pathology of the affection and explained how even when the condition was present at birth it failed to give rise to symptoms immediately because the pylorus was still unobstructed Later, under the influence of feeding, retention occurred, this caused enlargement of the mucosa, which further closed the pylorus and induced a muscular spasm The spasm increased the hypertrophy, and the vicious cycle thus created brought about pyloric obstruction The time required for this sequence of events varied from a fortnight to a month The symptoms varied with the degree of obstruction The mild cases should be treated medically, the severe cases operated upon at once He advocated early operation on all moderately severe cases, since by this means an anxious period from six to sixteen weeks was eliminated and the child was operated on when it was in the best physical condition He was convinced that if this were done the mortality from this affection would be infinitely small, as the majority of medical and surgical deaths came from this group in which there had been delay He described Rammstedt's operation, and emphasized the importance of giving saline solution intraperitoneally Either was

the anaesthetic used at his operations He had performed Rammstedt's operation on twenty-one occasions with nineteen recoveries, the two deaths occurred in greatly debilitated children

PATHOLOGICAL NEW GROWTHS

A MEETING of the Pathological Society of Manchester was held on November 11th, with Professor E D TELFORD in the chair

Professor SHAW DUNN showed a specimen of carcinoma of a bronchus associated with a large pulmonary abscess The tumour involved the main bronchus to the lower lobe of the left lung and had produced narrowing or occlusion of the airway The abscess, which contained about two ounces of pus, had developed in the portion of lung supplied by the obstructed bronchus, no doubt as a result of locking up of secretion with infection Professor Shaw Dunn remarked that it was not very uncommon to find a malignant growth of the bronchus or the bronchial glands underlying a septic pulmonary or pleural lesion in the adult

Mr P G McLEVEDY showed a specimen of adenoma of the common bile duct, removed from a man aged 62 There had been jaundice for three months, at first intermittent and then progressive After the first attack the jaundice completely disappeared Six days after the operation death occurred from haemorrhage from an acute duodenal ulcer The specimen showed marked dilatation of the common bile duct above the tumour, which on microscopic examination showed a simple adenoma Mr McLevedy also showed a large branched gall stone, two of the branches being over half an inch long There were several small branched gall stones in the same gall bladder, which was thickened and sclerosed Chemical examination of the stones showed a large proportion of cholesterol

Mr J ARNOLD JOYNS exhibited a microscope specimen of a section through bone removed from a case of chronic hyperplasia of the upper jaw He stated that the pathology of this condition was uncertain, it was termed a cancellous osteitis by some and osteitis fibrosa by others It had no connexion with tubercle, syphilis, or malignant disease It was distinguished from other bony tumours of the face and head such as acromegaly, leontiasis ossis, and osteitis deformans in being unilateral, affecting the upper jaw mainly on the alveolar margin and canine fossa, invading the maxillary antrum until it quite or almost disappeared, but leaving unaffected the nasal and orbital cavities Guthrie had pointed out the remarkable resemblance between the microscopic appearances of this condition and those of sections through the bony labyrinth in oto sclerosis It was unnecessary to sacrifice the upper jaw in treating this condition, removal of the tumour by the gouge relieved the symptoms and in most cases reduced the deformity to vanishing point

Specimens were demonstrated also by Mr JOHN MORRIS and Dr G D DAWSON

PYLOROPLASTY

At a clinical meeting of the Devon and Exeter Medical-Chirurgical Society at the Royal Devon and Exeter Hospital on November 19th, Dr R V SOLLY being in the chair, Mr NORMAN LOCK, in association with Dr N LOVELL, showed an infant in whom pyloroplasty had been successfully performed for congenital hypertrophic stenosis of the stomach

Mr Lock said that the operation performed was that commonly known as Rammstedt's, the hypertrophied and prominent pylorus being incised down to, but not through the mucous membrane The mucous membrane was then freed laterally from the musculature of the wall so as to come up into the incision, no attempt being made to suture Mr Lock added that the case would be of special interest to the meeting in that the operation had been suggested in the first instance and twice performed successfully by Mr Russell Coombe of Exeter, to whom acknowledgement had been made by Mr Tyrrell Gray in Carson's Surgery

Mr RUSSELL COOMBE said that in his first case of operation for pyloric stenosis in the infant he incised the

mucous membrane, but although the case was successful he wrote at the time to the *Annals of Surgery* saying that he would not go deeper than the muscle if called upon to perform further operations of that nature.

Dr N. LOFFET said the case was typical, the infant weighed 12 lb. at birth, there was early vomiting of the projectile character, and constipation with a clean tongue.

Dr W. GORDON advocated early transfer to the surgeon, when the typical vomiting and history suggested stenosis, and even if no tumour could be felt, which was often the case. He also showed a man in whom the physical signs suggested a congenital heart affection, the most probable diagnosis being latent ductus arteriosus. Dr Gordon illustrated the case with clinical notes, diagrams, and x-rays.

Mr A. L. CANDLER showed a youth on whom he had performed an extensive plastic operation after severe laceration and sloughing of the tissues of the palm of the right hand and ulnar aspect of the wrist. A "tubular graft" had been obtained from the abdominal wall, with excellent good union and vascularity. All the fingers had been saved with the exception of the little finger, and the new palm allowed excellent grip with full movements of all the flexor tendons. Mr Candler also showed the specimen and gave particulars of a tumour removed from a uterus. The growth was attached by a stalk to one corner, the stalk being formed of normal muscle, the lower part of the tumour being a sarcoma and the upper part formed of cysts of undetermined nature.

Dr R. V. SORRIS read a short paper on melanotic sarcoma illustrated by slides obtained from a recent case in the Royal Devon and Exeter Hospital.

THE SPAHLINGER TREATMENT FOR TUBERCULOSIS

At a general meeting of the Newport Medical Society held at the Royal Gwent Hospital on December 25th, with the President, Dr S. HAMILTON, in the chair, Professor S. LYNE CUMMINS, Cardiff, gave an address on recent treatments of tuberculosis. He described the work carried out in recent years by the medical staff of the Welsh National Memorial Association in the clinical testing of suggested remedies for tuberculosis. At the suggestion of the Medical Research Council and with the co-operation of Professor C. DREYER, F.R.S., the dihydrate vaccine had been carefully tried in about a hundred selected cases. In spite of the promising results claimed for the vaccine in the preliminary tests on guinea-pigs, the results of a year's clinical trials had been disappointing. Although a proportion of the treated cases had done well, the majority had shown no such degree of amelioration as could be claimed as a success for the dihydrate vaccine. A still more extensive trial of sodium nitrothiote, as suggested by Sir Leonard Rogers, F.R.S., had so far led only to inconclusive results, although several of the tuberculosis physicians had been so favourably impressed by its effects that they were continuing to use it. Moellgaard's smocrysin, a gold salt, a supply of which had been placed at the disposal of Professor Cummins by the Medical Research Council for clinical trials in Wales was now undergoing systematic investigation by several workers. The number of patients so far treated was but small owing to the fact that it had been found necessary to exercise great care in the selection of cases, but results of the highest interest had already been obtained and it was hoped to apply the treatment to a wider group of cases during the coming year. Professor Cummins illustrated by lantern slides certain aspects of treatment with smocrysin. In concluding his review of these experiments in the treatment of tuberculosis, Professor Cummins pointed out that, in every instance, the nature of the remedies under test had been fully and freely disclosed and that supplies had been provided free of charge in order that the truth might be brought to light. In every case, the authors of the treatment method at test had given their friendly co-operation and had loyally and frankly accepted the results.

Turning to the question of the Spahlinger remedies, the situation was, he said, unhappily quite different. Without desiring in any way to prejudice the ultimate decision as

to the value of these preparations, Professor Cummins pointed out that no clinical trial could be conclusive unless accurate information as to the strength of each serum and each vaccine were placed at the disposal of the medical profession. This information had so far been withheld. In none of the published case records was the dose stated, an omission which was fatal to any real weighing of the value of the records in question. Inquiries addressed by him to the best known of the British doctors who had tried the Spahlinger remedies had elicited the curious fact that not one of them had known the strength of the preparations they had employed, the doses having been arranged by M. Spahlinger on a system known to him alone. Professor Cummins illustrated the difficulty by asking how a pharmacologist could test the effects of tincture of digitalis if he were merely given solutions of this drug without any indication as to their strength.

A discussion followed in which Dr ROBERT JONES (M.O.H. Monmouthshire) said that he did not regret nor apologise for the fact that he was one of the chief protagonists for the trial of the Spahlinger remedies within the area of influence of the Welsh National Memorial Association, and that he would always welcome the opportunity of examining any treatment that would give relief and perhaps cure to the sufferers from tuberculosis. There were very good reasons why M. Spahlinger had not disclosed the technique of his remedies and the dosage of partial and complete serums in terms of antitoxic units, etc., as demanded by Professor Cummins. He had been strongly advised not to do so at this juncture by men who were clinicians of first rate importance who had so advised undoubtedly in the best interests of the tuberculous patient and of Spahlinger himself. It was to be regretted that there were instances on record where bacteriologists who had been privileged to see the workings of Spahlinger's laboratory not long afterwards let it be known to patients that they were going to prepare them a vaccine by Spahlinger's methods—an utterly impossible proposition. There was also on record Spahlinger's own reason why he had not published every detail of his process, it was that he was anxious that clinical proof of the value of his methods should first be conclusively demonstrated by more extensive clinical trials, because he felt that if other workers for any reason were unable to produce the results which he had obtained it would react disastrously on the future general application of his treatment. He stated that when these demonstrations had proved beyond doubt the efficacy of his system of treatment he was prepared to make known his methods and technique so that the treatment might be available in every country. As regards the clinical results, Dr Robert Jones differed from Professor Cummins in his interpretation of the records, and preferred trusting the clinician rather than the bacteriologist in this aspect of the matter. He was glad to note that the cases cited had been authenticated by consultants and physicians of repute, and in the large majority, whether of medical or of surgical tuberculosis, the treatment gave results in many cases striking and generally most favourable and very encouraging. Moreover, quite a number had been recorded as having had no relapse during a period of over six years. He had it on the highest authority that it was not the fact, as had been stated at the meeting, that the details of the technique of these remedies had been lost. The attitude of the Ministry of Health to these remedies was disclosed in its 1922 report. Dr MacNalty, a medical officer of the Ministry, visited the bacteriotherapeutic institute at Carouge, Geneva, in 1922, and as far as he was in a position to judge the clinical results of treatment, both by the serum and the vaccine were in some cases striking. It was intimated to M. Spahlinger through unofficial channels that, with his consent, the Ministry would be prepared to appoint a committee of recognized medical experts who would assess the results of his method in a number of cases to be selected by a physician nominated by him and after due trial, report on the value of the treatment. M. Spahlinger was informed that he would not be required to divulge the technique by which the serum and vaccine were prepared. What was now asked for in Wales was that the Welsh National Memorial Association should conduct a similar clinical test in some of its institutions, but this request Professor Cummins declined to concede until the

technique of the remedies, etc., had been disclosed to him. He demanded for Wales conditions which the Ministry had waived, or did not insist on at the outset, for the country generally.

Other speakers in the discussion were the CHAIRMAN, Drs H. W. Catto, W. K. BEAMAN, J. Frost, T. I. Candi, L. E. ACOMB, A. C. JOHNSON, and J. McGINN.

Professor CUMMINS replied to the main points raised regarding sinu-auricular, and, referring to Dr. ROGER JONES's criticism of his attitude towards the Sprahnger remedies, said that he and his colleagues of the medical staff of the Welsh National Memorial Association would gladly give to the Sprahnger remedies the same fair trial which had been given to other suggested treatments provided that adequate supplies of the serums and vaccines, together with the necessary information as to their nature and strengths, were placed at his disposal.

A vote of thanks to Professor Cummins, proposed by the CHAIRMAN and seconded by Dr. ROGER JONES, for his illuminating address was carried by acclamation.

Reviews.

MACKENZIE'S "DISEASES OF THE HEART"

THE new edition of Sir JAMES MACKENZIE'S *Diseases of the Heart* calls for more than passing notice because it is entirely rewritten, and because there is more in it than a book on diseases of the heart. The author desired in addition to secure other objects, which he enumerates as follows: (1) to recognize the position of medicine amongst the sciences, (2) to show the need for a new outlook in medicine, (3) to indicate the highest object of investigation—namely, the assessment of symptoms—and (4) to simplify medicine by rendering the phenomena of all health easy of comprehension through rigid adherence to fundamental principles. With this purpose in view he evolved a number of laws or principles governing the production of vital phenomena and pathological changes which must be grasped before the normal and the abnormal functioning of the heart can be appreciated. These principles include a study of the reflex arc, of vital processes and activities in the human body, of the laws of stimulation, contraction, conduction, inhibition, and control of cell impulses, and of the law of fluctuation. The principles are described and discussed very fully in the earlier chapters, and their application is illustrated in connexion with the various disorders and diseases of the heart later on.

The book consists of sixty-nine chapters. Their mere headings show how great a change has come over the outlook on the heart and its diseases. Twenty years ago the chief subject dealt with was valvular disease. In this book of 500 large quarto pages fifteen are devoted to the consideration of valvular defects. It might have been thought that the author had said all there was to be said about auricular fibrillation in the last edition, where the subject was dealt with in twenty-five pages. In the new edition it occupies fifty-six pages. Further experience has only confirmed the author in his well-known views that instruments (the polygraph and electrocardiograph) are means to an end, and should be used as such. Within recent years the tendency has been to lay stress on the value of electrocardiographic records as a measure of muscular contraction, myocardial disease, and cardiac functional power. Mackenzie would have none of this and characterized as vain and futile many of the interpretations of the records taken from the human heart. He seeks all through the book, which is fully illustrated by graphic records to show how far they can be correctly interpreted, and how the information thus gained can also be required by ordinary clinical examination. A new feature in this edition is the insertion of clinical records of individual cases to illustrate the various points which are being dealt with. Many of these had formerly been grouped in an appendix, but they

are much more valuable to the reader when used to illustrate certain main points in the text.

Mackenzie was a great believer in the scrap heap. When ever any view of his was found by himself or by others to be erroneous he scrapped it. During his lifetime he made a big scrap heap out of much of the traditional teaching on heart disease. There is a good deal of further scrapping in this book. The "all or nothing" law of Bowditch, from which it was deduced that when the ventricle contracted it did so with all the energy it possessed, is scrapped as merely an experimental and unnatural result. It is replaced by the law of fluctuation, which means that the functions of organs are so regulated and controlled that their response is always graded to suit the circumstances of the moment. Within recent years a somewhat popular test of the functional capacity of the heart has been the increase of the pulse rate after exercise and the time of its return to normal. This Mackenzie promptly scrapped, for all that it did was, he said, to demonstrate the excitability of the sino-auricular node, which varies much in individuals and in the same individual under varying conditions.

The name of James Mackenzie is specially associated with the condition known as auricular fibrillation and the proper use of digitalis in that disturbance. His earlier (and temporary) view was that auricular fibrillation was due to paralysis of the valve, and it is interesting to find that he returned to this view, although his explanation of it is entirely different. He did not regard the "circus movement" theory of auricular fibrillation as either illuminating or satisfactory. His final explanation of fibrillation was that there is a loss of the controlling influence of the sino-auricular node owing to disease, and that fibrillation of the valve results from this, as it does in all muscles cut off from the controlling influence of their nervous supply. Another interesting effect of the loss of control by the sino-auricular node is to be seen in the altered condition of the auriculo-ventricular node, which has now to resume the control of the heart beat. The a-v node "(1) becomes more susceptible to stimulation by the sympathetic and vagus nerves, (2) is subjected to a shower of impulses from the valve, and (3) does not meet the requirements of the body like the s-a node." These points are very fully discussed and their clinical importance indicated, as is also their relation to the wise use of digitalis in auricular fibrillation.

In the chapters on angina pectoris we have the result of profound study and personal experience. He has to deal with one of his favourite studies—pain—and he tells much of that subject, probably as much as is known, but he admits freely how much is unknown. He is writing specially for the general practitioner who has to deal with the patient, and he wishes first of all to impress on him the importance of a clear recognition of the pathology of the disease—that it is due to myocardial degeneration, the result of vascular disease. No drug or other treatment can be expected to alter this degeneration, but much can be done to prolong life by regulating the patient's activities in accordance with the functional powers of the heart. A careful distinction must always be made between true or primary angina and secondary angina, as he terms it, which is common in women as the result of nervous strain. The latter is a temporary condition which yields to treatment and is quite curable. There is no dogmatism in the statement of his views, and the difficulties which still exist about the pathology of angina pectoris are fully recognized, as the following sentence shows: "Although one can thus trace angina pectoris to the heart muscle, and although we can recognize from the various illustrations given that the voluntary muscles made to contract when deprived of blood give rise to pain, and although it can be demonstrated in many cases of angina pectoris that the heart muscle was deprived of blood, and that pain resulted when there was a demand for more blood, as on effort, yet it is not quite clear how these impulses which could not arise from a greatly increased number of muscle cells contracting gave rise to pain. The matter is left there for further consideration."

There is much that is left by the author for further consideration by the medical profession—left finally, for

this is his last contribution to medical progress. This pioneer has put on record the experiences of a lifetime in connexion with the study of diseases of the heart, and although much of Mackenzie's teaching is now universally accepted there are many fresh ideas of the same practical nature in this book. Having found that further progress as regards the heart was impossible by a study of the heart alone, he set himself in his later years to find out some general principles which would serve to explain the symptoms of diseased processes in the body. He expounded them and showed how far they apply in the explanation of cardiac problems. It is not easy to understand the principles or to follow their application, where so much is new. All careful readers will probably agree that no one save Sir James Mackenzie could have written such a book, which will stand for long as the best textbook on diseases of the heart, and for ever as marking a stage in the progress of medical science.

OPERATIVE CYSTOSCOPY

In his *Operative Cystoscopy*² Mr CANNY RYALL has incorporated results obtained during many years of study, and has presented them in an atlas with the hope that the reproductions of cystoscopic views and cystoscopic methods may stimulate others to obtain mastery in a branch of surgery that is becoming of greater importance each year. There are 528 illustrations in colour, and 670 in all. The great majority are from original paintings by Mr Thornton Shiels, and their reproduction in colour shows a very high level of workmanship. A feature of the work is the representation of successive stages during treatment, and particularly of treatment by means of diathermy. For example, Plates 67 to 76 consist entirely of drawings of a patient suffering from an unusual form of cyst, who was treated by means of diathermy applied through an operating cystoscope. The drawings, over fifty in number, represent the appearance of different portions of the bladder during and after the treatment of this patient. In many cases the representations of cycles of appearances in the bladder is instructive, but perhaps the author, in his relish for his subject, has been overlavish in his plates. Some criticisms may also be directed against some of the operative measures of which Mr Canny Ryall is a strong advocate. It is indeed doubtful whether an open operation is not preferable to some of the intrascopic methods illustrated in this atlas. But Mr Ryall is an enthusiast for operative cystoscopy, and his strong reaction against unnecessary cystotomies is easily understood. The majority of the plates illustrate conditions well known to cystoscopists, but a few, such as No. 105, show conditions that are very rare. In a work, however, that aims at completeness there is much to be said in favour of the inclusion of rarities.

The preliminary text is quite overshadowed by the plates. In it a simple description is given of the methods portrayed in the illustrations. Many of the instruments described have been modified by the author and bear his name. Some of them we know from experience to be excellent, but some will not find general favour amongst urologists. However, these are questions of individual preference, and it is outside the province of the reviewer to discuss the merits or demerits of any particular instrument or method advocated by Mr Ryall. It may, however, be interpolated as a criticism that Mr Ryall's manner of presenting his subject is somewhat reminiscent of certain Continental authors, with a strong individualistic flavour, and a dramatic touch that is seldom found in English writers. Nevertheless, Mr Ryall's industry and experience command respect, and as his faults are the result of extreme enthusiasm for his work they are readily pardoned.

The chief value of *Operative Cystoscopy* will be in familiarizing those who have a limited knowledge of the subject with the various appearances of the bladder in disease and during the course of cystoscopic treatment. The cost of the book will prevent its finding a place on the bookshelves of many individuals, but as a method of education in post-

graduate study it should be of the greatest use. The author, the artist, and the publishers are to be congratulated—the first on his industry and enthusiasm, the second on the skill with which he has portrayed what he has been shown, and the third on the quality of the reproductions.

THOMSON'S "CLINICAL STUDY AND TREATMENT OF SICK CHILDREN"

THE fourth edition of Dr JOHN THOMSON's well known book, *The Clinical Study and Treatment of Sick Children*,³ has appeared. The third edition was published in 1921, and contained 877 pages. The present volume contains 912 pages, and space has been found in it for a great deal of new matter. In the chapters upon infantile scurvy, rickets, encephalitis lethargica, purpura, spastic paralysis, sporadic cretinism, and the early treatment of mental defect, much that is new has been incorporated, and articles upon the exudative diathesis, erythroderma, cephalic bruises, arachno-dactyly, pyknolepsy, and hypertelism, subjects not previously treated, have been introduced.

It is not difficult to understand the reasons that have given this book its wide and rapidly growing circulation at home and abroad. Among physicians in this country who have devoted their life exclusively, or almost exclusively, to this branch of medicine, its author occupies a unique position. By his original contributions he has done a great deal to disprove a charge that is sometimes made against us as a nation—that we have been slow to develop an interest in or to further the remarkable advances in the study of diseases of childhood achieved in the last thirty years. Among workers in all nations he is recognized as a leader. To Dr Thomson the literature of the subject is well known, and a great part of the success of the earlier editions of his book was due to the way in which he placed his own observations and views in their proper relation to the observations of others or to views which obtain elsewhere. Throughout the book there are very many references which will help the student to make himself acquainted with many aspects of the subject in greater detail.

Yet all this is achieved without diminishing the great practical value of the book. It is a true clinical study, and for the most part a study of things that are common. The author's interest in the unusual has not diminished his understanding of matters of everyday occurrence.

EUGENICS

WE know of a case in which a man wittingly continued to propagate mentally defective children from an insane wife. Such cases are rare, and should properly come under the cognizance of the criminal courts. Probably, however, much more harm is done to society in the long run by the thoughtless and inconsiderate mating of individuals who are to all appearance perfectly sound. It is well known, at any rate by the majority of experienced people, that certain unions are apt to lead to disastrous results in the progeny, yet it may be doubted whether the consciousness of this fact acts as a deterrent in ninety-nine cases out of a hundred. It is part of the function of eugenics to correct this defect, and an indispensable preliminary to this end is to trace out, with such definiteness as is possible, the points where the strata of disease crop out in the succession of related generations. By this means material can be accumulated which would afford the means of making at least a rough estimate of the chances of a given disease reappearing in the offspring, and it is possible that definite laws would ultimately be discovered for our guidance.

Considering the importance of the subject, all work that enlarges our knowledge in this direction should be welcomed, and regarded as having something more than a merely academic interest. The recently published work of

³ *The Clinical Study and Treatment of Sick Children*. By John Thomson M.D. LL.D. F.R.C.P. Fourth edition rewritten and enlarged. Edinburgh and London: Oliver and Boyd, 1925. (Demy 8vo, pp. xxxii + 912. 258 figures. 50 net.)

Operative Cystoscopy. By E. Canny Ryall F.R.C.S. London: H. Kimpton, 1925. (Fcap folio. pp. xiii + 47. 670 figures. 115 plates. 70 net.)

Dr Stocks on *Hereditary Disorders of Bone Development*⁴ is a good example of such contributions to our knowledge. He has chosen two diseases, multiple exostoses and cleidocranial dysostosis, and on a basis of more than a thousand references has made a searching analysis of the hereditary influences at work in them. The former disease is characterized by the presence of abnormal thickenings and projections on the bones, often occurring in great numbers and affecting almost any part of the skeleton, although most frequently the long bones. Apart from the resulting deformity, symptoms may arise through pressure of the excrescences on neighbouring nerves. In cleidocranial dysostosis various deformities of the skull are met with, associated with a variable degree of aplasia of the clavicles. The disease gives rise to no serious functional disability, but it exhibits the curious physical sign that the two shoulders can be brought together into contact in front of the chest. Hereditary influence is strongly marked in these two instances of disordered growth, and they therefore form very suitable material for the study of the subject.

Although Dr Stocks has, naturally, adopted the standpoint of heredity throughout his work, and has traced the hereditary influence from every point of view, his book is by no means a collection of statistical tables and genealogical diagrams. The diseases are graphically described and well illustrated in a number of plates, and the reader gains an intimate acquaintance with conditions that are interesting in themselves, apart from any statistical deductions derived from them.

It is only by researches of this nature that we are enabled to obtain guidance in the important matter referred to, and the medical profession might profitably give somewhat more recognition to such work than appears to be the case. Dr Stocks's book is a monument of painstaking research, but we think it is somewhat disfigured by the quotation he has placed in the forefront of his book, which runs as follows: "If the same pains were taken in breeding mankind that gentlemen have bestowed upon the breeding of horses and dogs, human nature might, as it were, be new-modelled, hereditary diseases banished, and such a race might people the country as we can form no conception of. Instead of a nation of mongrels there would in time appear a nation of admirable Crichtons." Effort directed towards eradicating the recrudescence of disease is one thing, an endeavour to remodel the type of perfectly healthy individuals is another and quite different matter. However great the pains expended in the breeding of mankind, the attempt to emulate the results obtained in animals would be futile, since the same methods cannot be employed in the two cases. In animals the results are reached through experiments in mating, and we have not yet reached a stage of civilization in which analogous experiments in man are feasible. And however admirable the characteristics of parents or ancestors may be, we have no means of predicting that they will be transmitted in the offspring, experiment alone can decide that point. Should, however, eugenicists ever undertake the remodelling of our countrymen it is to be hoped they will not choose the celebrated Scotsman as a type, who do not want to be converted into a nation of bores.

NOTES ON BOOKS

MEDICAL men who were students at Cambridge between the years 1886 and 1918 will read with interest Mr J. R. M. BUTLER's memoir of his father's mastership at Trinity College. The volume is a mosaic of excerpts from Dr Butler's letters commented in commentary by his son. The chapters deal with the master's relations to college politics, university interests, religion, politics, and so on. The book is illustrated with portraits of Dr Butler at various stages of his mastership, and of these none will revive recollections more vividly than that which depicts the master with Sir

A. W. Ward, Master of Peterhouse, outside the Senate House. It is a tribute, no doubt to the health as well as the longevity of the master that amidst the numbers of distinguished men mentioned throughout the book hardly a single medical name occurs.

The *Synopsis of Special Subjects*,⁵ for the use of practitioners, is really four books bound in one. The first quarter, dealing with diseases of the skin, is written by Dr H. C. Semmon, the second, on obstetrics and diseases of women, by Dr Malcolm Donaldson, the third, on the ear, nose, and throat, by Mr Archer Ryland, and the fourth, on the eye, by Mr J. F. Cunningham. The preface modestly admits that the book cannot be commended from the literary or educational point of view, and with this we agree, for it is merely an extended list of causes, signs, symptoms, and remedies. The practical objective of the authors has been to set out specialized knowledge in synoptic form so that it may be quickly consulted.

We have received three volumes of the *Practical Medicine Series*,⁷ 1924—Vol. II, on *General Surgery*, edited by Dr Albert J. Ochsner, Vol. III, on *The Eye, Ear, Nose, and Throat*, edited by Drs Wood, Small, Andrews, and Sham-baugh, and Vol. V, on *Gynecology and Obstetrics*, edited by Drs Watkins and De Lee. These are concise practical books, of which eight volumes are published to cover the progress of medicine and surgery each year. They are well illustrated and indexed, and should be useful when a busy practitioner seeks for the most modern teaching on any of the special subjects with which these books deal.

*Health in Childhood*⁸ is a collection of five lectures selected from a series delivered at the Institute of Hygiene. The first lecture is on the care of the eyes in childhood, and is by Lieut. Colonel R. H. Elliot, M.D., F.R.C.S. (late I.M.S.). The second, on the care of the primary teeth, is by George Thomson, L.D.S., lecturer on dental surgery, Royal Hospital for Diseases of the Chest. The third is entitled "The prevention of infectious diseases in childhood," and is by Dr R. King Brown, lecturer on public health, Guy's Hospital Medical School. The fourth, on the prevention of physical deformities in children, is by the late Mr H. Græme Anderson. The last lecture is on the mental and moral education of the child, by Dr Charles S. Thomson, M.D., Deptford. The lectures are as interesting as their titles, and as good as the names of the lecturers would lead one to expect.

Dr JAMES S. VAN TESSLAAR, Brookline, Massachusetts, has published a translation into English of a book by Dr WILHELM STEKEL, one of the first disciples of Professor Freud. He is a very voluminous writer, and has now, as Dr Van Tessaar states in his preface, separated from Freud. The work is entitled *Peculiarities of Behavior*,⁹ and is concerned with Dr Stekel's views on wandering mania, dipsomania, kleptomania, pyromania, and allied impulsive acts. The book, he has published in German, are so exceedingly copious that even those who read German fluently and are interested in the subject may be glad to have this English version of his opinions on the subjects enumerated, in two easily handled volumes.

Lectures to Nurses, by MARGARET S. RIDDELL, is the second edition¹⁰ of a small manual containing a series of lectures to probationary nurses. The information given is intended to cover the field of instruction required by the General Nursing Councils for the State registration examinations. In addition to the routine lectures, there are notes on snaphography, insulin treatment, and diseases of ductless glands. The book opens with a few necessary and helpful remarks on hospital etiquette and personal hygiene. The author has had wide experience, and knows how to impart information in an interesting way. There is an index, and the chapters are clearly grouped and headed. The book should be of use to sister tutors, and all who lecture to probationary nurses.

⁴ University of London. Francis Galton Laboratory for National Eugenic. Eugenic Laboratory Memoir XXII. The Treasury of Human Inheritance. Edited by Karl Pearson. F.R.S. THE CENTENARY OF THE BIRMINGHAM MEDICAL SCHOOL

THE University of Birmingham will celebrate the centenary of the foundation of the Birmingham Medical School on Tuesday next, December 8th. The school dates from the establishment by Mr William Sands Cox of a course of anatomy, physiological, and surgical lectures, the first of which was given on December 1st, 1825.

The University will hold a congregation at 2.30 p.m. on Tuesday, when, in the unavoidable absence of the Chancellor (Viscount Cecil), the Vice-Chancellor (Sir Gilbert Bailing, Bt, C.B., F.R.C.S.) will preside. Honorary degrees will be conferred on the Right Hon. Neville Chamberlain, M.P., Minister of Health, Sir Donald MacAlister, Bt., President of the General Medical Council, Sir Humphry Rolleston, Bt., President of the Royal College of Physicians of London, and Emeritus Professor Priestley Smith, M.Sc., F.R.C.S. Eng., late Professor of Ophthalmology in the University. Mr Neville Chamberlain will then give an address. On the evening of the same day a reception will be held at the University buildings, Edgbaston.

HISTORY OF THE BIRMINGHAM MEDICAL SCHOOL

The first record of any teaching of medical subjects in Birmingham goes back to the year 1768, when Mr John Tomlinson, surgeon to the Town Infirmary, conceived the idea of publishing a quarterly journal of medicine. In this journal he states that there were a number of medical students apprenticed to the practitioners of the town and to the surgeon to the infirmary, and that, actuated by a desire for instructing these young gentlemen of the faculty, he attempted a course of anatomical lectures during the winter season. His whole scheme was included in twenty-eight lectures, given weekly, but he had to alter the course as the opportunity for procuring bodies occurred.

There is no record to show how long these lectures continued, but we know that Tomlinson continued his teaching after his appointment to the staff of the General Hospital in 1779. It is only right that Tomlinson's name should be handed down to posterity, for he was the first provincial surgeon to give regular anatomical lectures. That spasmodic lectures were given even before Tomlinson's course is obvious from this advertisement in *Aris's Birmingham Gazette*:

"October 23rd 1762.—The body of the malefactor who is ordered to be executed at Lichfield on Monday 25th instant will be afterwards conveyed to the house of Dr Darwin who will begin a course of anatomical lectures at four o'clock on Tuesday evening and will continue them every day as long as the body can be preserved and shall be glad to be favoured with the company of any who profess Medicine or Surgery or whom the love of science may induce.

This was Erasmus Darwin the grandfather of Charles Darwin. In November, 1765, at a meeting held at the Swan Inn, it was decided that—

A building for the reception of proper objects be erected within a mile of the Town of Birmingham with all convenient speed this building to be known as The General Hospital at Birmingham in the County of Warwick, for the relief of the Sick and lame poor.

Dr John Ash had initiated the idea of a hospital, and was largely responsible for its ultimate formation, but for some years such great financial difficulties were encountered that the building could not be completed, and it was not until 1779 that the hospital was opened. Dr John Ash (whose features are well known to us from the great picture by Sir Joshua Reynolds, which hangs in the hospital board room, and the famous engraving from this by Bartolozzi, which is reproduced here) was born in Coventry, took the M.A. at Oxford in 1746 and the M.D. in 1754. He settled in Birmingham in 1755, and soon became one of its most prominent citizens and a popular physician.

In 1787 he resigned his hospital appointment and moved to London. He became a Fellow of the Royal College of Physicians in this year, Censor in 1789-93, Harveian Orator in 1790, Goulstonian Lecturer in 1791, and Croonian Lecturer in 1793. He was also a Fellow of the Royal and Antiquarian Societies. He died in 1788, aged 75 years.

Another of the first four physicians appointed to the staff of the General Hospital was William Withering, who discovered the medicinal use of digitalis, and is known to fame as a great botanist, while the youngest of the four was Dr Edward Johnstone, who became the first president of the Birmingham School of Medicine, and who, before his death in 1851 at the age of 84, had seen the school firmly established.

The foundation of the Medical School was due to William Sands Cox, who was born in 1801. He was the second son of a local practitioner, Edward Townsend Cox, and after serving his apprenticeship locally, studied at Guy's and St Thomas's in London and various schools in Paris. *Aris's Birmingham Gazette* of November 7th, 1825, contained the following advertisement:

A course of anatomical lectures with physiological and surgical observations will be commenced on Wednesday 1st of December, 1825 at 12 o'clock. The course will be continued during the ensuing winter on Mondays, Thursdays and Fridays, at 24 Temple Row. This plan is made with the approbation of Dr John Bone, Dr Pearson the physicians and surgeons of the General Hospital, the Dispensary and the Town Infirmary and other distinguished practitioners.

Early in 1826 Mr Sands Cox received official recognition from the Society of Apothecaries as a teacher of anatomy, and for three years he taught some twenty students. Then, in 1828, the school was definitely established and a series of lectures in a number of subjects was begun, but for a year longer there was only one room for all the purposes of the school. Early in 1830, after a successful appeal for financial support to the "local patrons of science," a set of rooms was built in Snow Hill, and a library and an anatomical museum were provided. Then the building of the Great Western Railway forced the school to remove

ENDOCRINE THERAPY

THERE are few fields of therapeutics in which such important recent advances have been made as in endocrine therapy, and therefore the discussion on this subject in the Section of Medicine of the Annual Meeting of the British Medical Association, which is reported in this issue (p. 1051), is of particular interest, because it gives an opportunity of learning the prevailing expert opinion regarding our present knowledge of this rapidly changing subject. The progress of endocrine therapy has been marked by several brilliant discoveries of the greatest clinical importance, but it must not be forgotten that interspersed with these successes have been almost innumerable failures. Nothing illustrates the special difficulties of the subject better than the fact that the relation between the pancreas and diabetes mellitus was discovered more than forty years ago, that continuous research on the subject has proceeded ever since, and yet that only recently has a method of isolating the active principle been devised.

The successes of endocrine therapy encourage the clinician who is faced with the urgent necessity of curing sick persons to press forward along any line of treatment that appears at all promising, but the memory of the endless disappointments and mistakes of the past make the laboratory scientist working in this field particularly cautious and critical. Dr. Langdon Brown and Professor Swale Vincent, the two openers of the discussion, represented these two points of view very ably, and at first sight there may appear to be a serious divergence of opinion between them. The differences, however, have not quite as great a practical importance as might at first appear. Two separate problems were in reality under discussion: first, the question as to what substances of therapeutic importance can be extracted from endocrine glands, and secondly, whether the therapeutic actions produced are true substitution effects—that is to say, effects due to the endocrine extract replacing the secretion of some gland that is not functioning normally. The second of these problems is by far the more difficult, because our knowledge regarding the normal functions of the endocrine glands is only fragmentary, and it is extraordinarily difficult in many cases to prove with certainty that a given clinical condition is really due to the insufficient action of an endocrine organ. Fortunately, however, the first problem is of the greater practical importance, since, if it can be shown that an endocrine extract relieves or cures a recognizable clinical condition, then the preparation can be used in therapeutics and its exact mode of action left to be determined in the future. This point was well illustrated by Professor Swale Vincent when he pointed out how imperfect our knowledge still is regarding the mode of action of insulin. The fact that we do not know the exact relation between the activity of the islets of Langerhans and the occurrence of diabetes mellitus does not however, seriously interfere with the use of insulin in the treatment of this disease.

The chief differences of opinion between the two openers concerned the real nature of the effects pro-

duced by the administration of endocrine extracts, but in view of our present imperfect knowledge of the whole subject it would seem more profitable to concentrate on the simpler problem, and to try to determine what definite therapeutic effects can be produced by endocrine therapy. This knowledge is of outstanding practical importance; moreover, its acquisition offers one of the best avenues for the approach of the more complex problem of the exact mode of action of endocrine organs. As regards this more modest problem of the therapeutic activity of endocrine extracts there was a very firm unanimity of opinion among the speakers in the discussion. All speakers, of course, agreed on the powerful and obvious therapeutic actions that can be produced by thyroid extract, insulin, adrenaline, and the extract of the posterior lobe of the pituitary body. Moreover, it was agreed that the recent work of Collip on the parathyroid, and of Doisy and Allen on the ovary, promised to bring the extracts of these two organs into the same category. These workers have devised methods of preparing relatively pure preparations of the active principles of these glands, and have shown that the activity of the extracts can be demonstrated by definite biological tests. Past experience has proved that when once satisfactory methods have been devised for extracting the active principle of an endocrine organ and for testing the activity of the extract, it is usually not very difficult to ascertain the therapeutic value of the preparation. The actions of extracts of the anterior lobe of the pituitary gland also are becoming established with some certainty, in this case the activity of preparations can be tested by their action on amphibian metamorphosis, and Dr. Gardiner Hill has reported that the preparation produces definite and measurable therapeutic effects on metabolism in certain abnormal conditions.

The importance of sure tests for the activity of endocrine preparations needs to be emphasized, for unfortunately nearly all the active endocrine principles are extremely unstable. Even with such preparations as insulin and extracts of the posterior lobe of the pituitary, for which methods of extraction have been thoroughly worked out, it is still impossible to prepare extracts that can be relied on for clinical use without routine biological standardization of the products. Experience with the better known extracts suggests that in the case of other extracts, unless there is some method for testing the activity, it is a mere chance if any commercial preparation contains the active principle. This view is supported by the fact that Collip obtained negative results with all the commercial preparations of parathyroid that he tested, and Doisy and Allen had similar experiences with ovarian extracts; moreover, workers who have tested preparations of the anterior lobe of the pituitary have found a large proportion to be inactive. These facts are quite sufficient to account for the wide divergence of results that has attended the therapeutic application of these endocrine preparations. There seems, therefore, to be a very general agreement that active principles with recognizable pharmacological actions and definite therapeutic activity can be obtained from at least seven different endocrine organs—namely, from the thyroid, the parathyroids, the two lobes of the pituitary, the islets of Langerhans, the medulla of the suprarenal glands, and the ovaries. The important rider must be added, however, that most of these active principles are very readily destroyed, and that unless their preparation is controlled by some test for their activity, commercial

extracts of the endocrine glands will often be found to be inactive

The use of endocrine preparations is attended with a further difficulty in that a suitable means of administration must be discovered. There seems to be good evidence that the active principles of the thyroid, parathyroid, and anterior lobe of the pituitary can all be absorbed from the gut, that insulin is not absorbed from the gut, and that at most only traces of adrenaline and posterior pituitary lobe extract are thus absorbed. The available evidence seems to show that the active principle of the ovary also is not absorbed from the gut.

As regards orchitic extracts, there appears to be a very general agreement that ordinary commercial extracts produce no therapeutic action, although results quoted by Professor Langmead suggest that a method of producing an active extract may soon be available. Testicular grafts or injections of emulsions of freshly excised testicles can, however, produce temporarily beneficial therapeutic actions. The evidence regarding testicular grafting was reviewed by Mr. Kenneth Walker, who concluded that such grafts do not grow, but, on the contrary, rather rapidly disappear, and that the beneficial effects observed are due to the absorption of the active principles present in the graft.

Perhaps the most instructive feature of the whole discussion was that no one advanced any evidence that any endocrine preparations except those enumerated above produced any therapeutic effect whatever. The discussion showed that extracts with therapeutic actions could be obtained from the seven endocrine organs already mentioned, but that in only three instances was the active principle absorbed from the gut in significant quantities. Furthermore the evidence quoted showed that the majority of commercial preparations of ovaries and parathyroids do not contain any active principle, and there is also evidence that the same is true of preparations of the anterior lobe of the pituitary. In the light of these facts it is an instructive exercise to go through the list of preparations of any of the more enterprising advertisers of endocrine preparations and to calculate what percentage of them are likely to produce any therapeutic effect whatever. This unfortunate background of irresponsible commercial exploitation cannot be wholly ignored in any discussion on endocrine therapy for the mass suggestion exercised by intensive and skilful advertisement tends to swing public opinion towards undue credulity, and therefore drastic criticism is particularly necessary in this field of therapeutics. The task of the critic is always an ungrateful one, and it is satisfactory to note that most of Professor Swale Vincent's audience appreciated the useful function he was performing in applying rigorous criticism to the difficult problems of endocrine therapy.

MACKENZIE'S LAST WORK

Two books have appeared this year containing the last teachings of two great pioneers in medicine. The one is *Neurological Fragments*, in which the scattered articles published by Dr. Hughlings Jackson have been collected by Dr. James Taylor into a single volume. The other is *Diseases of the Heart*, by Sir James Mackenzie, which is reviewed this week at page 1068. He was occupied with the correction of the proofs of this book on the day of his final seizure. In it will be found described all those researches into cardiac

disease which have added so much to our knowledge and made Mackenzie's reputation world wide. But there is much more than this. Twelve years have passed since the last edition of his textbook was published. During those years he did not rest content with his previous discoveries, to him they had seemed only to lead on to deeper problems. As he expressed it, doubts began to arise in his mind during those years with regard to the sufficiency of the researches that had been made, and were still being made, by himself and others.

Although recognizing that physiological laws and facts must be the key to pathological problems, Mackenzie failed to find in physiological textbooks information sufficiently explanatory of the changes met with in disease, and he found much which he considered to be directly opposed to the facts of clinical medicine. For the elucidation of many cardiac problems he required some fresh guiding principles of a general character—that is to say, applicable to the whole body and to all forms of disease. In his later years he was concerned to set out those principles which he regarded as physiological laws and to apply them more especially to the work of the heart in health and in disease. Thus when he came to write the new edition of his book he in a sense, produced two books blended into one. He was a general physician expounding many new principles of normal and diseased function in the human body which he had evolved as the result of his own thought and experience. But he was also a heart specialist applying those principles to the study of disorders and diseases of the heart. He may have been right or he may have been wrong about his new principles, but Mackenzie had in the past an uncanny knack of being right. His earlier work was ignored for many years and it is to be hoped that English workers will not ignore this later work and will not leave it to be appreciated first of all in other countries.

The heart used to be regarded as a simple single organ at which when it went wrong the physician discharged a drug known as a cardiac tonic and all was expected to go well. In his previous writings, so many of which this *Journal* had the privilege to publish, Mackenzie had disposed very thoroughly of this view of the heart but in the new edition of his volume he enlarged and altered all views as to the various functions and activities described as cardiac action. Much of his previous work had dealt with the disorders of the so-called "conducting tissues," a term he discarded and replaced by "the genetic system." This system extends from the sino auricular node to the terminal filaments of the auriculo-ventricular bundle in the wall of the ventricle. It was formerly regarded merely as a conducting system, transmitting impulses from the sino auricular node as a telegraph wire conveys electrical messages or a nerve fibril conducts an impulse. Mackenzie established the fact that the genetic system is much more than this. It is a wonderful piece of vital mechanism capable of regulating itself and the muscular contraction of the ventricles capable of being affected by nervous influences and altered blood conditions, and when disordered giving rise to definite signs. The genetic and the muscular (contracting) systems of the heart are associated in their working and the one must not be considered apart from the other. He compared the relation between these two systems to that between a voluntary muscle and its motor nerve, and said that a movement of the heart could not be understood without a knowledge of the genetic system, or the function

a garden, now a lawn of rest in a busy world, here will be found an old half-timbered house disguised with later accretions until it has lost all trace of its antiquity.

Nottingham has always been famous for its gardens, and the fame of Nottingham rose growers is world-wide, to day on all sides can be seen large areas of land laid out in small gardens in which every variety of fruit, vegetable, and flower is to be found growing, and growing well. The open spaces of Nottingham are more extensive than those of any other town, the beautiful Forest, now a large recreation ground, was once the town racecourse, before that it was part of the common land of the town, and along the top of its steep slope was a line of picturesque windmills which have now disappeared. Then there is the Arboretum, laid out in formal beds and pleasant grass slopes, with ponds and avenues—a pleasant spot within five minutes' walk of the centre of the town.

A quarter of a century ago lace making was the staple industry of the town, and a district of large warehouses is known as the Lace Market. Now, however, fickle Fashion has turned her face against lace and a cloud is over this once flourishing industry. Other trades have come. There are Player's vast cigarette and tobacco factories, Boots Pure Drug Company direct from Nottingham a great trade which now covers almost the whole of England, and in the eye and motor world there is the Raleigh Company. I and R Morley's hosiery works find a home in Nottingham, and there are other great businesses too numerous to mention.

Nottingham is exceptionally well provided with railways. Her two main stations are served by the London, Midland and Scottish, and the London and North-Eastern railway systems, and from both there is a splendid service of express trains. London is reached in two and a quarter hours, Manchester in two hours, Leeds in just under two hours—in fact, there can be few towns with a better service of trains to all parts of the country.

Since the war a great deal of building has taken place on all sides of the town, and large areas which were formerly waste are now covered with good modern houses. The problem of providing arterial roads is being tackled, and soon it will be possible to avoid the centre of the town by those who wish to do so.

Education is much to the front. There is the University College, which is hoping in the near future to become the East Midlands University. Through the munificence of Sir Jesse Boot a magnificent site has been provided between Nottingham and Beeston, and here university buildings are being erected, which will be second to none in the country. Sir Jesse Boot has also laid out large recreation grounds, tennis courts, football and hockey fields, a boating lake, and

has provided the town with the largest open air swimming bath in the country.

Nottingham possesses a cemetery of more than ordinary interest. Standing on the top of the hill adjacent to the Forest, the Church or Rock Cemetery is a very picturesque with its curves and steep slopes. It is, in fact, as beautiful as a cemetery can well be.

Castle Rock, Nottingham

show, colt-nut-shy, and menagerie. For three days pandemonium reigns, and day and night are made horrible with the raucous voices of organs blasting forth their tunes in loud-toned rivalry. But Nottingham enjoys it, though it often pretends that it does not. Before the war excursions used to bring visitors from all parts of England, and even now crowds come in from distant places and give themselves up to thorough, if rowdy, enjoyment. The fair is opened formally by the Mayor, according to the ancient charter, on the first Thursday in October, and continues until midnight

on Saturday. By Sunday all is clear. The caravan has folded up its tents and silently stolen away, and peace reigns once more.

In the field of sport few towns and counties can show such a record as Nottingham. On the cricket field Notts has won for herself an honoured place, which the present members of the county eleven are doing their best to maintain. The past contains names known wherever cricket is played: Arthur Shrewsbury, William Gunn, Alfred Shaw, Richard Drift, Mordecai Sherwin, William Barnes, Wilfred Flowers, William Attewell, J. A. Dixon, and A. O. Jones, to mention a few. We are rather prone to think that the men of the present are lesser figures

than the giants of the past, but Notts occupies a high place among the counties in the championship table, and among her team are men who, we hope, will be seen in the England eleven against Australia next year. At football, too, Nottingham has a record any town or county could be proud of. Association football of the first class is now mainly a game for professionals, and the length of a club's purse rather than local genius is the deciding factor. Rugby football is, comparatively, a new game in this district, but here, as elsewhere, we are forging to the front.

St. Mary's Church, Nottingham

Nottingham is exceptionally well supplied in the matter of hospitals. The General Hospital has, since the war, been very hard put to it to make both ends meet. Thanks, however, to the generosity of the citizens of Nottingham, it has been able to carry on its good work with undiminished energy. The present premises have been all too small for some years, and the site at the corner of Park Row and the Ropewalk, formerly a reservoir, has been secured and a new out-patients' wing, with complete orthopaedic and x-ray departments, together with a thorax and nose block for both out- and in-patients, is being erected, and will probably be opened by the middle of next year. When this is finished Nottingham will have a hospital of which any town would be proud.

The Children's Hospital occupies a fine site overlooking the Forest, and here again lack of space has been a trouble, but this is being remedied by a rebuilding on the old site, when finished there will be room for sixty beds. Until recent years there were two women's hospitals in the town. These two—the one in Castle Gate and the Samaritan—have now amalgamated, and great efforts are being made to equip the Women's Hospital fully, so that it may be in a position to meet the heavy demands put upon it. A fine site has been secured in Peel Street, and next spring building operations will begin, when finished the hospital will contain sixty beds. The Eve Infirmary, on the Ropewalk, is a new building with an absolutely up-to-date equipment, and the Thorax and Nose Hospital also, in Goldsmith Street, is exceptionally well fitted up.

At Bagthorpe, on the north of the city, is the Bagthorpe Infirmary attached to the workhouse, where every care and attention is given to those who are taken there. It is a modern building with everything that can be desired in the way of equipment. Near by is the Isolation Fever Hospital.

In addition to the above there is a Home for Surgical Tuberculosis at Bulwell, and a small Venereal Diseases Hospital for Women on Gregory Boulevard. Early next year it is expected that the new Clinic of the Cripples' Guild will be opened in Park Row. No trouble or expense has been spared in making this as up to date as possible, and when finished it will be a very valuable addition to this side of the city's medical and surgical amenities.

Such, then, is the modern city of Nottingham. Visitors to it are always impressed by its cleanliness and beauty, for the billiness of its streets gives it an air of variety which so many modern towns lack owing to their flatness. The next article will deal with the history of the town.

TREATMENT OF RHEUMATISM IN INDUSTRY

LONDON CONFERENCE OF THE INTERNATIONAL SOCIETY OF
MEDICAL HYDROLOGY

A SPECIAL meeting of the International Society of Medical Hydrology was held at the house of the Royal Society of Medicine on November 27th, jointly with the Section of Balneology and Climatology of that body, to discuss the treatment of rheumatism in industry.

Dr GUSTAVE MONOD, M.R.C.P. Lond (Vichy, France), who presided, referred to the widening scope of the International Society, which was a federation of the societies interested in medical hydrology in the various countries. He added that in France it was the view that as soon as Germany joined the League of Nations German bodies should be admitted to affiliation with all the learned societies, and it was now proposed to open the door of this International Society to their German colleagues (Applause). Dr Monod added that, with regard to the subject before the present conference, in France the question of rheumatism had not the national importance which it possessed in other countries. In the French working class as a whole chronic rheumatism was not prevalent, the large hospitals in Paris and elsewhere did not publish statistics with regard to this disability, nor provide special accommodation. He attributed the relative immunity to the fact that France was blessed with sunshine.

The Problem in Great Britain

Sir GEORGE NICHOLSON conveyed the congratulations of the Ministry of Health to the International Society on its

efforts to grapple with this formidable and protean disorder. The Ministry had prepared some kind of survey of the incidence of rheumatic disease among the insured population of Great Britain. In this country they were losing—or were spending on sick benefit, which must be regarded as equivalent to loss—not less than £2,000,000 a year on this group of diseases, and the annual loss of time involved was three million weeks, or 60,000 years. This represented quite a serious burden upon the State as the more definitely recognized scourges like cancer and tuberculosis, but it was only in recent times that the dimensions of the problem had been appreciated, and therefore the measures taken to solve it were as yet inadequate. It was because of this inadequacy that so many of the cases found their way into Poor Law hospitals. It was necessary to apply much more careful and accurate methods both in the discovery of the cause, whether it be infection or metabolic change or anything else, and in the measures to be taken for its removal. It was not enough to make a frontal attack, dealing with the palpable and obvious manifestations of the condition, the foci of infection must be sought, and the disorder grappled with in a scientific and effective way. This necessitated team work, the association of men engaged in different branches of study and practice, some of whom would concentrate on the teeth and oral conditions, others on the abdomen, others again on the genito-urinary tract, and so forth. The raising of the powers of resistance against the cause of the malady, whether infective or metabolic, had to be considered. In treatment as well as in diagnosis co-operative effort was necessary. The group of measures for the alleviation of pain, the increase of absorption, the re-education of muscles, thermal, electrical, hydrological treatment, every kind of treatment likely to place the body in a position to make its own resistance to the causal conditions predisposing to this disease, called again for team work. The evidence of this morbid process as it appeared in childhood must be studied, for the principles of preventive medicine should be applied in the earliest years of life. All this seemed to point to some special kind of institution which would meet this national problem. There were already available a few large spa hospitals, of all of which good use might be made in combating this disease, but he looked for some concrete suggestions from the conference, the deliberations of which would receive earnest consideration from the Ministry.

Reports from Northern European Countries

Dr J. VAN BRFEMEN (director of the Instituto for Physical Treatment, Amsterdam) said that in Holland official statistical data with regard to rheumatism were unknown. Although the number of rheumatic patients was very great, the scientific and social study of this condition was in his infancy. In his institution at Amsterdam both private and insured patients were received, and the principal successes were obtained with the latter. Private patients mostly came at a late stage of the disease, and did not always finish their cure, but panel patients, as the result of an arrangement with their sick funds, obtained free medical treatment by physical methods, and so came early, with quite excellent results. Every year about 1,000 patients with chronic rheumatic diseases were treated at the institute, and another 1,000 sent to spas or treated in their own homes. The general treatment was by heat and electric light baths, douche massage, and the mercury lamp, and local treatment by massage, diathermy, local baths, and exercises. The establishment of clinics and laboratories for methodical research in rheumatism was most desirable. In his experience every occupation had its distinctive rheumatism.

Dr HANS JENSEN (Bispebjerg Hospital, Copenhagen) said that in Denmark also there had not yet been set on foot a really systematic movement to combat chronic rheumatism. Among those receiving sickness benefits in a large industrial insurance scheme 12 per cent of the males had this disease. Of the persons declared to be permanently invalided from whatever cause, 14 per cent were disabled by chronic arthritis, while pulmonary affections accounted only for 13.5 per cent. No public hospitals in Denmark were devoted specially to this disability, but

TREATMENT OF RHEUMATISM IN INDUSTRY

interest in the question was being aroused, and the study was being followed up in many directions.

Dr. G. KALLMÄR (consultant, Pensions Hospital, Stockholm) said that chronic articular rheumatism held the dominating position in Sweden as a cause of disability, exceeding even pulmonary tuberculosis. Every year about 1,500 persons in Sweden were treated under the auspices of the Board of Pensions for articular rheumatism. Sweden had many small spas, but these were neither big enough nor good enough for the purpose. There were also four institutions for medical treatment established by the Board of Pensions, in these between 700 and 800 cases of chronic articular rheumatism and about 100 cases of sciatica were treated annually. Only those patients who had a chance of becoming self-supporting were admitted, and about 60 per cent were discharged cured. The general hospitals, which were community-owned, were generally so overcrowded with other cases as to be able to make only a small contribution to meet this need. The urgent necessity was for special hospitals. A committee for combating rheumatism had been established in Sweden, and the question of providing a central hospital for rheumatic diseases in Stockholm, in immediate connexion with the university clinics, was being considered.

The Case for Clinics
Dr. FORTESQUE FOX (London) said that sufferers from chronic rheumatism were in very many cases instances not suitable for in-patient hospital treatment, they came up for treatment in out-patient departments, or special clinics, or they went to spas. Rheumatic cases had to be treated from many sides, in a large number, for instance, there was an infective element which ought to be removed, and vaccine or drug treatment was of the greatest benefit in many cases. But those who treated these cases were constantly aware of the underlying fact that rheumatism was a climatic disease, that it was induced by damp and cold, and that a great deal could be done to counteract the effects of climate by the right use of waters and baths. He was of opinion that all the British spas could be criticized, but after a long experience he was convinced that it was true. The fact was that all these places, however much they might differ in the quality of their waters, had one method of treatment in common in their well appointed bathing establishments. For a certain number of cases recourse to the spas was desirable and important, but in a large proportion the provision of clinics, under skilled medical direction, to which some of the features of spa establishments might be adapted, would meet the case. In this country the campaign against rheumatism could proceed with a double aimment—there was something that could be done at the spas and something outside the spas. The external methods of treatment should be made available in towns, apart from spas, by means of rheumatism clinics. The advantages of clinics had already been tested in connexion with various forms of disablement. At a clinic an intensive study of a group of maladies could be carried out, and the cases would sort themselves almost automatically into categories. The necessary conditions for the success of such clinics, which acted to advantage not singly but in combination, (2) facilities for records and measurements, (3) the services of a skilled medical director, and (4) liaison with research establishments.

Dr. L. J. LLEWELLYN (President of the Section of Balneology and Climatology) also spoke in favour of clinics. The climate of this country would not adapt itself to the rheumatic subject, and therefore he must adapt himself to it. There was nothing which could so raise the resistance to this malady as discriminating hydrotherapeutic procedures. A campaign similar to that already undertaken in the case of tuberculosis should be organized for the purpose of dealing with rheumatic disorders, for the report of the Ministry of Health furnished an index to the magnitude of this invalidity. He gave some interesting statistics obtained from the United States, and mentioned that in New York there were 48 "cardiac clinics," as they were

called, 20 in Philadelphia, and 142 in the whole of the United States. The results obtained showed that not only the earning capacity of adults but the school attendance of children had increased to such an extent as to represent a monetary gain far exceeding the cost of supervision. The elucidation and treatment of rheumatic disorders was a public health problem of the first magnitude, and a national scourge must be dealt with by a national policy. He favoured the establishment of hydrotherapeutic centres in all the great cities.

Dr. M. B. RAY (London) said that the insured population of Greater London and its environs was 2,400,000, on the basis of the Ministry of Health's report, the number of these people who were likely to seek advice each year for one or other forms of rheumatic disorder was about 60,000. In London and district there were nearly 4,500 cases of rheumatoid arthritis of varying severity, and it would be quite safe to suppose that the number of sufferers from the non-articular forms of rheumatism tickled the number of those suffering from chronic arthritis, and provision must also be made for osteoarthritides. He estimated that there were about 22,000 insured persons in the London district alone who could be regarded as likely to benefit from a more enlightened treatment, for, of course, it must be remembered that a large proportion of the total number of sufferers were beyond praying for, a living reproach to the policy of *laissez-faire* which had been adopted in the past. A certain number of the cases required definite in-patient hospital treatment. No comprehensive scheme could possibly neglect that side of the question. Another important point was that satisfactory research into the causation of many of these cases could only be carried out on patients who were constantly under observation. It was neither possible nor desirable to afford in-patient treatment to anything like all that they needed in a properly equipped clinic, in close relation to an out-patient department, and with a research department available. Dr. Ray then gave a detailed sketch of such a clinic and its equipment. Under the arrangement which he showed, forty-four treatments of various kinds—douches, vapour and slipper baths, packs, manipulations, and ionization therapy—could be given in an hour. Such a clinic in a large centre of population would be a clearing house from which suitable cases could be drafted to the spas. Dr. FRANK KORNLIANN (Riez, Switzerland) gave some account of the clinics in Switzerland, which had proved quite satisfactory. The treatment provided took the form of baths, electricity, ionization, and massage. The light and early cases were often entirely cured, the chronic cases were sometimes cured, but more often proved intractable. Of the cases treated at one such clinic, about 20 per cent were of chronic articular rheumatism.

Spa Treatment
Dr. KERR PRINGLE (Harrogate) described the facilities available at the several hospitals in Great Britain entirely devoted to hydrotherapeutic treatment, where 93 per cent of the cases treated were rheumatic cases.

	Beds	Patients (annual)
Bath, Royal Mineral Water Hospital	136	1,200
Buxton Devonshire Water Hospital	10	—
Belmont's Mineral Water Hospital	300	Nearly 4,000
Droitwich, St. John's	40	630
Harrogate Royal Bath Hospital	150	2,500
Stratcliffe	15	80 or 90
Woodhall Spa, Alexandra Hospital	30	188

At all these hospitals there were waiting lists, and a large number of cases every year had to be refused admission. In addition there was a hydrotherapeutic hospital at Southport, with 80 beds, dealing with 715 cases annually, but he had not particulars of the treatment given. He proceeded to an analysis of the cases treated at Bath, Buxton, and Harrogate on the lines of the groups of rheumatic conditions given in the Ministry of Health's classification. In Bath it was noteworthy that the proportion of osteo-arthritis to the other cases was 12 per cent in men and 6.9 per cent in women, in Buxton the figures for the sexes were respectively 6.6 and 8 per cent, and those given by the Ministry of Health respectively 8 and 9 per

cent. The Ministry drew attention to the larger proportion of female cases, but the Bath figures, apparently, were not in accord with this, no case should be labelled osteoarthritis unless verified by x-rays. On the general question of spa treatment, the importance of environment had to be taken into consideration. To take a patient from a manufacturing town and put him in a place like Bath, Buxton, or Harrogate was itself very advantageous. Practically all cases of fibrositis benefited from the employment of immersion baths given slightly above the point of thermal indifference. At the spas cases of fibrositis and neuritis in general gave good results within a few weeks, in chronic joint cases it might be a matter of months, and even then it was often only a question of degree.

Dr C. W. BUCKLEY (Buxton) said that rheumatic cases might be divided into four groups: (1) cases of rheumatic fever and its sequelae, these could be dealt with in any well equipped institution; (2) fibrositis of muscles, nerves, or joints, a group which reacted better to spa treatment than any other; (3) rheumatoid and osteoarthritis, for which spa treatment was not specific in itself, but was chiefly limited to the treatment of stiffened and disabled joints, and (4) gout, which reacted more effectively to the course of treatment at a suitable spa than to any other method. The methods of treatment might be grouped under three principal heads: (1) measures directed to the cause of the disease, which might be infective, metabolic, or traumatic; (2) measures directed to increasing the patient's powers of resistance and general health by tonics, diet, and improvement of home conditions; (3) measures directed to the removal of associated disabilities and pain. These could only be satisfactorily obtained at the present time for the industrial classes at spa hospitals, but much might be done in this respect elsewhere, given a well organized scheme. The resources of the great spa hospitals were not used to the best advantage, partly because of the method of selection of patients, for the most part on subscribers' recommendations, partly because of the limited period for which patients could be admitted, and partly again because no system existed in the majority of cases for ensuring the continuance of treatment at home on right lines. In every town of any size centres should be established to some extent on the lines at present adopted for tuberculosis. These centres might be developed in connexion with existing hospitals, and they should be able to command the services of a doctor of special experience for consultation with the patients' doctors, also facilities for special examination and investigation, and the provision of various physical methods of treatment, including electricity and massage. Such centres would be clearing-houses from which patients could be sent to spas for courses of treatment. The centres would also be able to exercise some supervision over patients at home, as was done in the case of tuberculosis centres, and to arrange for general hospital treatment where required.

Professor A. TILGHMAN (Rumania) furnished a brief account of the various Rumanian spas which receive cases of arthritis and so-called secondary rheumatism. At the principal spas necessary treatments in the shape of diathermy, electric light baths and mechanotherapy were provided. Some form of public assistance enabling spa treatment to be procured was given to certain classes of the community. Civil servants could be treated at the three State-owned spas at greatly reduced fees. Insured working people could apply for treatment at a marine sanatorium, with 300 beds. Provision was made at three spas for the treatment of soldiers. The uninsured poor were treated in Red Cross sanatoriums and at one of the State spas.

In the course of some desultory discussion, Dr MAX BÉRE (Germany) cordially reciprocated the kind words spoken by the President at the beginning of the conference. Medicine, he said, was an international concern, and he hoped that Germany, which had many workers in the science of hydrology, would shortly be able to co-operate with other nations in this particular field.

Mr W. A. APPLETON (Secretary of the General Federation of Trade Unions) said that according to the certificates from 6 to 10 per cent—varying with occupation and locality—of industrial sickness was due to this class of disorders, but he believed the certificates did not reveal

the full dimensions of the problem. He had hoped that Sir George Newman that morning would have indicated some practical means of which the approved societies could take advantage. The approved societies would not mind whether any movement was of a State or a voluntary character so long as something was done towards easing the heavy burden on their funds.

The President (Dr Monod) said that the suggestions made in the discussion would be considered later in the day by the council of the International Society and afterwards by the various national committees.

France.

[FROM OUR SPECIAL CORRESPONDENT.]

Economic Conditions of Life of French Doctors

AN inquiry made quite recently has thrown a melancholy light on the economic position of practitioners in this country. In agricultural districts, which alone are living on real values—that is to say, on the fruits of the soil—the easier situation of the peasant since the war enables him to pay his doctor at something like a reasonable rate. While the cost of living has increased six times, medical fees have increased four times. Though the doctor is impoverished, he can live. His average income is equivalent to £660 a year. In industrial areas where expenses are out of all comparison higher, and eat up half the receipts, the situation has become very much more difficult. From motives of economy the sick do without medical treatment. Yet fees have not been more than doubled. It is calculated that a practitioner who before the war had an income of £1,400 now has the equivalent of £550 only. On such an income he cannot bring up a family. The situation is particularly difficult in Paris, as must be the case since it has one doctor to every 660 inhabitants. Some of the figures are eloquent, for example, in the department of the Pas de Calais the midwifery fee is 30 francs (5s.), and in Corsica 10 francs (1s. 8d.). The effect of the social insurance law will be to render the practice of our profession still more difficult and less remunerative, and the State will gain nothing by having thus created a new proletariat.

A Strange Lecture

It is a pity that a more suitable place than the hall of the Faculty of Medicine could not have been found for the lecture given by Dr Semachko, professor of social hygiene in the Moscow Faculty. Let me, however, hasten to say that admission was by invitation only, and that the doors were closed to students. The subject on which the eminent professor spoke was artificial abortion, and the guardianship laws which favour it in the Soviet paradise. The audience piqued itself on being well educated, and the teaching of this new gospel did not provoke any protests, only, when Dr Semachko had finished, the dean of the faculty did not make his customary little speech, and the lecture ended amid icy silence. We shall have a warmer welcome for M. Roubakine, who is being sent to us by Russia as a sort of sanitary ambassador. His task will be to set going arrangements for holding sanitary conventions, to organize scientific congresses, and to supply to institutions concerned with medicine and pharmacy information with regard to these subjects. Russia announces also that it intends shortly to rejoin the Office International d'Hygiène Publique in Paris, with which it has not been connected since the revolution of 1917.

The Electric Stethoscope

A new and interesting piece of apparatus was presented recently to the Faculty of Medicine. It is a loud speaker stethoscope, which amplifies the sounds of the heart and lungs, separates them, and by means of "filters" eliminates all other sounds than that to which the observer wishes to listen. It was brought to France from America by Dr Lo Mee and Dr Helle, and seems to be less a medical invention than a contrivance perfected by telephone engineers. The audience which crowded the amphitheatre saw a patient, stated to be suffering from Bright's disease, while the din of the loud speaker filled the hall with the sound as of a charge of cavalry. It is easy to conceive the value such

an invention may have for teaching, but imagination can look forward to a time when the specialist shall sit at his fireside, pipe in mouth, and telephone receiver at ear, examining patient after patient with whom he is successively connected by the telephone exchange. Better still, we can suppose the auscultatory sounds registered on photographic discs and collected to form a cardiopathic library. The doctor of to-day must be a chemist, to-morrow he will have to be an expert in physics also. It will not be easy for our successors to obtain their medical qualifications!

Wine and Gout

Ever since anaphylactic phenomena became known the idea that they might have something to do with the acute attack of gout has seemed not without probability, and Professor Chrouff has assimilated the attack to shock. A rather entertaining experiment, one which would have delighted Sydenham, has just been made by Vidal and his pupils. They have used the skin reaction to test the sensibility of gouty persons to wine. It is known that certain wines will set an attack of gout going, and that subjects sufficiently courageous, or sufficiently greedy, to try the experiment a typical haemoclastic crisis (leucopenia, inversion of the leucocytic formula) has been produced again and again by small doses of burgundy, whereas medoc has no effect. The skin reaction has the advantage that while its result is clear, it is harmless, so that it can be repeated with all the different vintages. Out of 19 tests, the reaction was slight in 13, absent in 3 and very intense in 3. One of these was a woman in whom at every trial burgundy determined a violent attack of gout. Two circumstances lent particular interest to the experiment: first that the skin reaction is observed only in gouty persons and secondly, that the reaction does not follow all wines, but only some, and these always the same. The red wines of Burgundy (Chateaufort du Pape) give positive results whereas negatived results are yielded by the white wines of Burgundy, the red wines of the Medoc—except St. Emilion—the wines of Champagne and Madeira, and, surprising fact remembering its sinister reputation in England, the wine of Oporto. In 33 control cases, healthy persons or patients suffering from non-gouty affections, a positive result was given in only 5 instances. What the noxious substance is was not determined, it is not alcohol, nor is it tannin. On this head ignorance is complete. It may be asked whether it is some chemical property common to certain wines of differing geographical origin. It is tempting to answer in the affirmative since the skin reaction classifies wines in the same order as the palate. Every expert in wine will say that there is no basal similarity in flavour between the red and white wines of Burgundy, while the wine of St. Emilion (Medoc) is, in bouquet, first cousin to Pommard (burgundy). It would seem that the palate is a more delicate instrument of chemical analysis than the most refined laboratory procedures.

Canada.

[FROM OUR SPECIAL CORRESPONDENT]

Dr. V. T. MacEachern
The honorary degree of Doctor of Science has recently been conferred by Marquette University, Michigan, on Dr. M. T. MacEachern, who is a Canadian, and graduated in medicine at McGill University. The granting of this degree is of special interest because it is the first time that an honour of this kind has been conferred for hospital administration. At present Dr. MacEachern is director of hospital activities and associate director of the American College of Surgeons, with headquarters in Chicago.

Tuberculosis Sanatorium

After a prolonged delay the tuberculosis sanatorium at Ste. Agathe Quebec, has been again opened for the reception of patients. Originally under the administration of the military authorities, this institution has now been taken over by an association formed for the purpose—the Laurentian Sanatorium Association, Incorporated. The repairs, which were considerable, however, were undertaken by the Quebec Provincial Government. This sanatorium will accommodate several hundred patients, but will be

devoted mainly to the care of Protestant patients. A large sanatorium is to be built in the neighbourhood of Montreal, which will take care of the needs of the Catholic portion of the community.

The Criminal Insane

Steps are being taken to remedy certain conditions affecting the handling of the criminal insane in Quebec Province. At present the insane criminals are either kept in confinement jails, where they have special quarters or they are placed in ordinary asylums under special care. Much objection—not unreasonably—has been made to the latter plan, it is estimated that there are in the various asylums of the province at present some 300 criminal insane. The Provincial Government, therefore, has under consideration a scheme for completing two unfinished wings of the provincial jail at Bouchard. This will provide accommodation for about 400 criminal insane.

Hospitals in the Middle West

The following details are of interest as showing the rapid growth of hospital activities in Winnipeg. During the year 1924 the Winnipeg General Hospital treated 21,000 patients, over 12,000 of whom were admitted to the ward, the remainder being cared for in the out-patients' department. Analysis shows that in the last twenty years of this hospital's existence the average period spent by a patient in hospital has been reduced from nineteen to fifteen days, and that the mortality rate has been cut in two. The trend of the hospital's service has to some extent been a reflection of the condition of the community. The ratio of private and semi-private patients to public patients has been almost reversed in the last four years, the demand now being much more heavy for the public wards. The total cost of maintenance for the year was 718,000 dollars.

Private Hospitals

The Provincial Legislature of Alberta has passed a bill which is designed to correct certain abuses existing in several private institutions. Private hospitals must now possess a licence, there must be a resident superintendent, and a register is to be kept and inspections allowed. Operations are not permitted in places where accommodation can be obtained in approved hospitals, unless and until the consent of the Department of Health has been obtained. An approved hospital is one approved of by the Minister of Public Health, but this does not imply that it becomes a public hospital.

Alberta

The Chiropractic Board of Alberta will hold the first examinations for licence to practise towards the end of this year. All applicants must have a preliminary education equal to that required for entrance into medicine in Alberta. Chiropractors in this province must be licensed before they are allowed to practise. The Alberta Medical Association is to take up with the Provincial Department of Health the question of an amendment to the marriage laws, whereby it is suggested that some restrictions will be placed on the marriage of physically and mentally unfit persons.

Cancer

Some interesting statistics are now available regarding the incidence of cancer in Canada. They have become available owing to the great improvements effected of late years in the methods of notification, classification, and analysis of vital statistics. The figures deal with sixteen Canadian cities, which in 1921 had a combined census population of 2,220,000, the returns from these cities are limited to the last fifteen years. In the twenty years down to 1924 the deaths from cancer increased in the first decade at the rate of 14.5 per 100,000, whilst in the last decade the increase was 60.1, and for the second decade for the first decade was 60.1, and for the second decade 80.1. It has been shown before that in the United States the annual increase in the cancer death rate is about 2.1 per cent, and this corresponds very closely with the 3.1 annual increase shown by the Province of Ontario, for example.

It has been conclusively established that the number of cancer deaths annually for the whole of Canada is about 6,000. The best measure available at the moment of the

"cancer tiend" in Canada is a consolidated return of certain Canadian cities, beginning with ten cities in 1910, it included sixteen in 1923, but diminished to fourteen in 1924. The total increase is impressive: in 1911 the rate was 58.6 per 100,000, in 1924 it was 98.1, and this for all practical purposes corresponds to the combined cancer death rate of the United States. There is a striking difference between the rates: Montreal, Ottawa, and Quebec showed relatively low rates in a period in which other Canadian cities showed huge increases. This is held by some to be because the French Canadian population are less liable to cancer than the population of British origin, a view which is worthy of investigation. Amongst the Indian population there is an even more striking comparative absence of cancer, this has been borne out by investigations made in North, Central, and South America, and by the result of extensive correspondence with physicians working on the Indian reserves.

Ontario

The Banting Research Foundation has recently been established in Toronto with a view to discovering means for the prevention and also for the cure of diseases at present regarded as incurable. This foundation is a corporate body separate from the University of Toronto, the funds of the latter, largely supplied as they are by the Province of Ontario, are distinctly for the purpose of training students and developing the members of the university staff. The university has no means available with which to investigate problems brought to it by independent workers, or to aid workers in other universities or colleges. The funds for the support of the foundation are to be raised by a special committee, headed by the Right Hon. Sir William Mulock, the response to the appeal has so far been most encouraging. It is thought that the income from 500,000 dollars will suffice for some years to come, it is proposed to make the money available for the aid of medical men who have reasonable problems, who will either work independently or in any other university in Canada. For the work of the foundation space is available in the laboratories of the University of Toronto, and also in some of the other Canadian universities. Neither Dr Banting nor Dr Best will receive anything from this foundation. It may be added that both of these gentlemen have renounced all rights to any income from royalties or patent rights from the sale of insulin.

Certain amendments have been made in the legislation on medical affairs in the Province of Ontario, due largely to suggestions from the Premier of the province and the Hon. W. F. Nickle. The old Ontario Medical Act of 1923 is repealed, the definition of the practice of medicine is removed from the new Act of 1925, all drugless healers are placed in a class by themselves, and the use of the terms "doctor," "physician," and "surgeon" is forbidden to them, unless, of course, they are properly qualified practitioners according to the Ontario Medical Act.

Certain changes have also been made regarding the relations of practitioners to the Ontario Temperance Act. The number of prescriptions for alcohol which may be issued by any medical man in one month has been reduced from fifty to thirty, and it is now a statutory offence, punishable by fine, to exceed this number. Previously the breaching of the regulation only brought the offender into conflict with the License Commission Board and the Discipline Committee of the College of Physicians.

South Africa.

HEALTH PROGRESS IN JOHANNESBURG

THE report on the health of Johannesburg for the years 1922-23 and 1923-24 contains also a review of the public health conditions and progress in the city from 1902 to 1925. In this Dr Charles Porter, who has been its medical officer of health during that period, and is terminating his connection with the municipal council, takes the opportunity

of presenting what may be called a valedictory account of his work. With praiseworthy pride he records the fact that with its exceptionally low death rate and splendid climate, Johannesburg is entitled to rank among the healthiest cities in the world. It has a mixed population, estimated in 1922-24 as 162,000 whites, 121,344 natives, 10,904 Europeans, and 5,355 Asiatics. The death rate of the white population has fallen from 17.5 per 1,000 in 1905 to 9.76 in 1923-24, and of the natives from 33.6 in 1910-11, the highest recorded, to 19.06. The European and Asiatic populations do not, however, show the same progressive improvement, their death rates have remained high, and were 29.43 and 26.70 respectively in 1923-24. Nevertheless, the decrease for the whole population is marked, for in 1903-04 it was 23.9, and in 1923-24 had fallen to 14.61. The birth rate among whites is comparatively high, although slightly decreasing in recent years, and the infantile mortality—81 per 1,000 births—low. On the other hand, the mortality of mothers in childbirth is unsatisfactory. It reached 3.47 per 1,000 births in 1923-24—a high mortality rate, which is attributed to the lack of any district midwifery and training organization. A phenomenal decrease is shown in the incidence of enteric fever from 6.26 per 1,000 of white population with a death rate of 0.64 for the five years ending June 30th, 1908, to 0.81 case and 0.11 death per 1,000 in the five years ending June 30th, 1924. For many years before and during the South African war enteric fever had its home in South African cities. The Johannesburg statistics are therefore convincing proof of the value of the extensive sanitary measures instituted by the health authorities. Full and detailed accounts of these are given in the report. While other diseases show decrease, there has been a steady increase in deaths from cancer, among whites the mortality rates in each of the five-year periods from 1903 to 1923 was 0.43, 0.42, 0.62, and 0.70 per 1,000. In 1923-24 it had risen to 0.78. Nearly half of 1,252 recorded deaths from this disease were due to cancer of the stomach. The natives are mostly young adults, and the cancer death rate among them—0.08 per 1,000—was consequently small, but it is interesting to note that more than half of 171 of the deaths were due to cancer of the liver. Dr Porter includes in his report a valuable review of the measures taken during the last sixty years to combat miner's phthisis and pneumonia among native mine workers. For the first time in mining history a special course of training for mining officials in mining hygiene was recently instituted by the Witwatersrand University in conjunction with the mining industry. Another interesting section of the report deals with venereal disease, its notification and prophylaxis. An extraordinary outbreak of gonorrhoeal ulcers and vaginitis among girls of 6 to 10 years of age is recorded as having taken place in an exceptionally well administered children's home. The infection was traced to a girl of 11 years of age who had "run wild" with men.

CARDIAC MORTALITY IN SOUTH AFRICA

Dr Eustace Cluver, professor of physiology in the University of the Witwatersrand, in a paper read recently to the Witwatersrand Branch of the British Medical Association, challenged the prevalent view that the altitude of Johannesburg predisposed to an increase in the death rate from heart disease. As the result of careful statistical inquiry he found that the cardiac mortality was higher both at Capetown and Durban than in Johannesburg, and that, moreover, the Johannesburg mortality compared very favourably with that of England and Wales. During the last five years the Capetown rate had not altered very much, but in Durban, and even more so in Johannesburg, there had been a relative and absolute improvement in this respect. Allowance had to be made for the fact that the population of Capetown included more elderly people than that of Johannesburg, and it was also possible that differences in the relative distribution of the sexes might affect the cardiac mortality. It appeared certain, however, that altitude could not fairly be considered an important factor in the cardiac death rate.

INFANTILE MORTALITY IN KIMBERLEY

The annual report of the medical officer of health for Kimberley for the year ending June 30th, 1925, draws

¹ Report of the Medical Officer of Health for the years 1922-23 and 1923-24, and Review (1925) of the Public Health Conditions and Progress of Johannesburg. By Charles Porter, M.D., LL.D., D.P.H., Johannesburg. Radford Adlington Ltd., July, 1925. (Folio pp. 39, 1 chart.)

attention to the infantile mortality rate, which is still unsatisfactory. In urban areas the European ratio is 89.3, as compared with 17.8 in the rural, but the coloured infantile mortality was 194.1 in the urban areas and 166.1 in the rural. Conditions are still worse in the native population, the figures being 330.9 in the urban districts and 298.1 in the rural. The very difficult economic conditions in Kimberley during the year prevented much attention being paid to maternity and child welfare work, although special efforts were made to assist expectant mothers. Voluntary assistance is asked for, but it is pointed out that the maternal mortality is very low, and it is unlikely that pre-natal influences play a prominent part in causing the infantile mortality. The birth rate in the urban area is 22.4 in the case of Europeans, 41.0 for the coloured, and 22.0 for pure natives. Plague broke out in November, 1924, and between then and June there were eight cases with five deaths. Active measures were taken in the threatened area until the epidemic was stamped out.

Scotland.

THE SCOTTISH BOARD OF HEALTH AND EXTENDED MEDICAL BENEFIT

THE official evidence of the Scottish Board of Health before the Royal Commission on National Health Insurance has recently been issued. It contains proposals with regard to alterations in the scope of the scheme as it concerns Scotland, and the evidence of the representatives of the Scottish Board, Sir James Leishman and Mr. G. W. Wight. In connexion with the possibility of increasing the present insurance contribution, it was pointed out that a recent Act, which will come into operation at the beginning of 1926, added in effect to the insurance contribution, and accordingly the Board could not put forward any proposition involving an extra contribution just now, because the condition in Scotland was, from an industrial and economic point of view, serious, involving very heavy public burdens. It was believed that the present insurance service, so far as it related to health, was defective, and that the present medical service was merely a general practitioner service. In order to get the full benefit of the scheme for the health and efficiency of workers it was imperative at the earliest possible moment to extend the service so as to include, not only general practitioner treatment, but also all proper aids to diagnosis and second opinions in the way of specialists, physicians, and surgeons, as well as certain services which might be broadly described as curative, in that they were related to such methods as electrical treatment, light treatment, and similar special methods. In Scotland it was hoped that it would be possible to secure a certain measure of institutional treatment, including operative treatment. A complete scheme would also include dental treatment and convalescent treatment, but these things had had to be dropped, because it was not considered that the money available would provide them just now. It would be very valuable could the finance of the national health insurance scheme permit help to be granted to the voluntary hospitals in Scotland, if they were to continue to be an integral part of the medical machine. The estimates available had been founded on certain assumptions and certain figures, and in particular it had been assumed that the people concerned would be willing to realize that the country, generally speaking, was not too well off, and that there was not a bottomless purse into which everyone could dip his hand and extract as much as he could take out. In other words, it would be necessary to arrive at reasonable arrangements with everyone concerned on a fair basis. The real position in Scotland was that, so far as secondary services were concerned, co-operation with the voluntary hospitals was involved. While voluntary hospitals were in a position to finance the present commitments and the present services, they were not in a position meantime to finance the addition of what was really required. There were large waiting lists and a great inadequacy of beds. If the insurance side could make a substantial contribution towards its share of the use in beds, this would go a long way towards helping

the voluntary hospitals to provide such a service as would adequately meet the needs of Scotland. With regard to paying wards, if moderate charges were made to cover the fairly reasonable cost of first-class services, this would certainly meet a great want of the middle classes. It was believed that, in order to supply the deficiency of hospital beds in Scotland, something like £1,750,000 or £2,000,000 would be needed as capital expenditure, and a similar amount would afterwards be required for maintenance. The estimate of the cost of a complete dental benefit available to the whole insured population was something like 7s. 6d. per insured person per annum. The estimates, however, varied very much, and 7s. 6d. a head, which would mean something like £600,000 in Scotland, would probably be the rate for the first year and a half, after which the cost would tend to fall.

PUBLIC HEALTH ARRANGEMENTS IN EDINBURGH

Owing to a heavy incidence of scarlet fever among the population of Edinburgh the medical officer of health has sent out a notice to practitioners advising home treatment of cases of scarlet fever in every suitable instance in order to prevent overcrowding of the wards in the Municipal Infectious Diseases Hospital. Inunction of the skin with eucalyptus oil is advised among cases treated at home, and attention is drawn to the fact that, in the meantime, "observation cases" of scarlet fever cannot be accommodated in the Infectious Diseases Hospital. No common source of infection in the present epidemic, such as milk supply, has been discovered.

Attention is drawn in another circular to extensive outbreaks of food poisoning which have taken place during the past year in Aberdeen, Dundee and other places. To enable the public health department to locate the source of mischief in possible future outbreaks in Edinburgh, notification of suspected cases of food poisoning to the medical officer of health is requested. It is pointed out that recent experience has shown that delayed notification in suspected cases of food poisoning has created difficulties, both in tracing the actual source of infection and in dealing satisfactorily with "carriers." It is also pointed out that food poisoning is not, at the present day, regarded from the standpoint of the action of ptomaines and that such outbreaks are usually provoked by special micro-organisms. While a particular form of food, such as milk, cream, cheese, or flesh, may show evidences of decomposition, infection is due to the special organism associated with the decomposition, and early notification is of special importance so that agglutination tests may be carried out with the blood of affected persons in order to determine the special food-poisoning organism responsible. The Public Health Committee of the Edinburgh Town Council has agreed to pay a fee of 2s. 6d. for immediate notification by medical practitioners, and has promised to exert every effort to render assistance in collecting suspected material for bacteriological investigation.

HOUSING AND INFECTIOUS DISEASE

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on November 27th, with the President, Dr. J. C. McVail, in the chair, Dr. A. K. Chalmers read a paper entitled "National death rates in relation to national differences in housing." Dr. Chalmers pointed out that while the urban housing of Scotland was mainly of the tenement type, that of England was mainly of the cottage type and recalled the late Dr. Niven's remark that Manchester was, broadly speaking, a city of cottages. Dr. Chalmers exhibited a series of statistical tables contrasting the death rates of Scotland for various causes with those of the main subdivisions of England and Wales. He pointed out the consistently higher death rates of Scotland for most infectious diseases, and emphasized the contrast with respect to measles, which, in Scotland, was almost wholly a disease of cities. Dr. Chalmers also called attention to the difficulties of comparison introduced by the fact that the rules of tabulation when joint causes were stated on the death certificate were not the same in the two countries. The paper was discussed by Dr. Major Greenwood, Dr. Janet Lane-Claydon, Dr. J. A. Glover, Dr. K. E. Tappin, Dr. T. Crumwath and the President.

England and Wales.

VITAL STATISTICS FOR 1924

THE Registrar-General's *Statistical Review of England and Wales for 1924*, Part I, Medical, was issued on December 1st. It is an octavo volume containing 500 pages, and can be obtained from the Stationery Office, price 15s net. The birth rate, which since 1920 has shown a continuous decrease, was 18.8 per 1,000 persons living in the year 1924, being 0.9 per 1,000 below that of the previous year, and with the exception of the war years 1917 to 1919 the lowest birth rate on record. The death rate reached the lowest point hitherto recorded in 1923, last year it rose by 0.6 to 12.2 per 1,000 persons living, the increase being general at all stages of life. This increased rate was due entirely to high mortality during the first quarter of the year, when the death rate was 16.6, as compared with 13.2 in the corresponding period of 1923, the rate for the remainder of the year was below even the low record for the previous years. Infant mortality also showed a slight increase over that in 1923, which was 69 per 1,000 births and the lowest on record, the rate last year was 75 per 1,000 births. The death rates from diphtheria and from all forms of tuberculosis were the lowest, and those from cancer and from encephalitis lethargica were the highest, on record. The mortality from influenza was more than twice as high in 1924 as in 1923, but the changes in the mortality of other epidemic diseases were comparatively small. measles, scarlet fever, whooping-cough, and diphtheria all showed small decreases, the death rate from enteric fever rose from 12 to 13 per million persons living.

MEDICAL CARE AT WEMBLEY EXHIBITION

Statistics are now available regarding the first-aid work at the British Empire Exhibition, which was carried on by the St. John Ambulance Brigade and the British Red Cross Society in alternate months. During the past year 16,134 cases of illness were dealt with, of which 194 were serious, as compared with 23,388 cases in 1924, of which 400 were classed as serious. The dispensary, for which the British Red Cross Society was entirely responsible, took charge of 5,125 children this year, as compared with 11,091 last year. Ambulance cars were at work by day and night throughout the exhibition, and a medical officer and first-aid attendants were always at hand in the arena during all ceremonies and performances. The general arrangements for the year were similar to those in 1924, which were described in our columns of May 24th (p. 927) and August 9th, 1924 (p. 242).

Correspondence.

INFLAMMABLE TOYS

SIR,—I have recently been interested in the subject of the large number of inflammable toys and other articles which are being sold in toyshops and stores in London.

As a member of the council of the Institute of Hygiene, I invited their attention to the subject, and a number of tests were made. Each article was laid on a metal sheet and a lighted match was brought in direct contact with it, within three seconds the article was in every instance alight. Some of the experiments are recorded in the accompanying table.

Spontaneous Ignition Tests

In addition to the contact ignition tests, a test for spontaneous ignition was conducted.

A doll (3 in high costing 3d) was advanced towards an open gas radiator. At a distance of 3 in dense white fumes were evolved. At 2 in these ignited in a burst of flame and the doll was consumed in a few seconds.

I am indebted to Mr. Seymour Harding, the secretary of the Institute of Hygiene, for much valuable help in the matter of these experiments.

It is a good many years since I have bought toys, and the matter would never have come to my attention but for the fact that my interest in them was revived on behalf of my grandchildren. The appalling damage that could be done to a small child by the intense white heat evolved by these semi-explosive toys can easily be imagined.

Cont. of Ignition Tests

Article	Length	Cost	Height of Flame	Time of Combustion
1 Pocket comb	3 ¹ / ₂ inches	6d	18 inches	35 seconds
2 Dressing comb	7 ¹ / ₂	6d	over 20	33
3 Swinging parrot	6 ¹ / ₂	1s	18	45
4 Floating duck	1 ³ / ₄	2d	10	15
5 Infant's rattle	7 ¹ / ₂	9d	3 ¹ / ₄	50
6 Soap box		6d	24	30*
7 Doll	4	4 ¹ / ₂ d	15	25
8 Ball	2 ¹ / ₂	3d	15	10†

* Remained smouldering, 80 seconds.

† Remained smouldering, 10 seconds.

Note.—The rattle (item 5) consisted of a 2 in ball suspended in a hollow tubular loop intended to be fastened to the infant or its cot by a ribbon or cord.

On the occasion of my bringing this matter before the council of the Institute of Hygiene, a member informed us of a patient who had suffered severely owing to one of these inflammable combs having taken fire in her hand, with the result that the outer table of her skull was charred.

I would ask that other medical men would be kind enough to make known any instance illustrative of the danger of these inflammable toys and other articles. The volume of business done in them is very large. The shops are full of them, and the assistants make no secret of their inflammability. When I have asked what material they are made of I have been told "celluloid" or "vulcanite." I do not know how far these answers are correct, but probably they are substantially so. In any case the almost explosive inflammability of these toys is beyond dispute.

I understand they come from abroad, and there will be considerable opposition to any measures destined to do away with the danger. If, however, the case is as strong as it appears to me to be, I feel sure that the medical profession can do a great deal in the matter.—I am, etc.,

R. H. Elliot, M.D.,
Lieut. Colonel R.F.S. (ret.)

London, W 1 Nov. 20th.

PREHISTORIC TREPHINING

SIR,—Before Dr. Wolfel published his paper in *Anthropos* (in German) he wrote me a private letter in English (November 25th, 1923) giving me the lines he intended to follow and the objects he had in mind when placing this paper before ethnologists. As Dr. L. A. Parry, in his letter to the *British Medical Journal* (November 21st, p. 977), has rather misunderstood Dr. Wolfel's aims and meaning from, I fear, the manner in which this was presented by your annotator (November 7th, p. 857), I would wish that Dr. Wolfel should be fully and rightly appreciated. When a fifty-page article in one language has to be read and reviewed in another, discrepancies sometimes occur, and I think I can clarify the misunderstanding, as I have for many years taken special interest in this fascinating subject. In the course of his letter to me Dr. Wolfel says:

"The object of my own paper is to fix the cultural relations of trephining in accordance with the methods of modern ethnology. I carefully investigate all the elements of material and mental culture that accompany trephination all the world round. For I think this the very method to decide the origin and meaning of this curious practice."

These, of course, are the soundest principles to follow in antiquarian research. He goes on to say:

"Prehistoric Europe of course is the greatest difficulty as it has left us only the skulls, the stone implements and nothing more. As yet I cannot say anything decisive regarding it as I am very careful in concluding. The result reached by me is only that there is nothing to speak against the prehistoric European trephination to have been of other origin and of other cultural relations than trephination in Oceania and America. It is beyond my modest abilities to settle finally the question of European Stone Age trephination, but I hope some enlightened prehistorian will take advantage of my work to try the solving of the question with regard to Europe."

The reasons for the practice of trephination of the living human skull during the age of stone culture are so

varied in different countries and at different periods that great care has to be taken in any attempt to summarise by sweeping statements.¹ In South America, notably Peru, a large number of trephined skulls have been discovered. By far the larger number of these had been treated with surgical intent for fractures, no doubt produced by clubs in brittle contest. Photographs of some of the best of these can be seen at the Wellcome Historical Medical Museum. The skulls are supposed to be of Incan or pre-Incan origin. These races knew no metals beyond copper, gold, and silver, and they sometimes used a mixture of these three which was known as *champi*. That the implements used in these operations were made of stone is unquestionable. Small fractures which only needed a small quadrilateral piece of bone removed exhibit a diagram on the skull such as one observes in a child's game of "noughts and crosses."² The larger fractures—and there are some extremely large ones—have been heroically dealt with by sawing away the fractured portions in quadrilaterals and trimming up the edges. These cases invariably died. But there are other ancient Peruvian specimens which show no sign of fracture. They present a totally different appearance. The holes are rounded for the most part and are bevelled at the exposure of the outer table of the skull, downwards and inwards towards the lunum. These have been done by scraping the bone either with sharp flint or obsidian flakes. In some skulls there are two such holes, in others three, and in one case no fewer than five.

What was the reason for these latter daring and skilful, though usually successful, operations on the living skull of man? It is difficult to say, far more so indeed than to decide the reason for the similar specimens discovered in Neolithic France. The whole point seems to hinge upon the presence or absence of any human amulet in the interment. While large numbers are frequently found associated with burials containing Neolithic trephined specimens in French dolmens, none are found among the remains of the ancient Peruvians. I have written somewhat fully about this subject elsewhere.³ There is no doubt about the fact that epilepsy, severe chronic headache, and one might add vertigo, noises in the head, and Meniere's complex of symptoms (if such there were in those distant days), must have been decisive indications to the Neolithic savage that a devil was present in his head and clamoured for freedom. A hole was scraped with a flint flake through the cranium by the tribe's witch doctor, and I dare say, as often as not, some relief was obtained. There are reasons for believing that special prestige was associated with an epileptic, as also a lunatic. Were they not individuals out of the common and therefore should they not be venerated? If such a man were successfully trephined a greater prestige awaited him. Immense value appears to have been put upon a trephined skull in France, and we find that portions of such a skull bearing a fragment of the healed trephined ring of bone were abstracted from the skulls in the dolmens after death and were used as amulets. A hole or a groove in these amulets bears witness to the fact that they had probably been suspended from the neck of another who had likely enough suffered from the same affliction as the dead man had. In time this practice developed—or shall we say deteriorated?—into a fetish. There is no doubt it became most fashionable, as sometimes the larger portion of a tribe gave proof of having had such operative interference. Certainly the nature of this kind of prehistoric trephination was of ethical and not of surgical origin.

I think, therefore, we may conclude that the scraping method when employed in ancient Peru (when not associated with fractures) was done with surgical motives for a medico-physical complaint, while the operation upon those men whose skulls were found in the megalithic dolmens in France was performed for religious and spiritual reasons

on account of, presumably, ethical disorders. Therefore it would follow that both Dr Wolfel and Dr L. A. Parry are right, but each is dealing with different primitive methods of trephination in different parts of the world.—I am, etc,

T WILSON PARRY, M A,
M D Cantab, F S A

London, N 8 Nov 22nd.

SIR,—Mr L. A. Parry's surmise (BRITISH MEDICAL JOURNAL, November 21st, p 977) that this operation was performed by our Neolithic ancestors for reasons other than medical or surgical ones is probably correct, otherwise how are we to account for those instances where the operation has been performed in prehistoric times after death has occurred?—a fact which has been recognised. Trephining possibly was done to alleviate the symptoms of a depressed fracture—a very probable injury in those days when the end of every individual, like that of most wild animals of to-day, was a tragedy, and when belief in a natural death did not exist, or, again, to relieve those symptoms of nervous complaints which were supposed to be due to the influence of evil spirits. But it is most likely that in many instances the operation was a piece of religious ritual, comparable to the curious crosswise mutilation along the lines of the sagittal and coronal sutures which was noticed within recent times amongst the Loyalty Islanders, and is similar to the "sincipital T" described by Manouvrier in Neolithic female crania from the district of Sanno-et-Oise. This would account for the removed portions of bone being used as amulets.—I am, etc,

Bexhill on Sea, Nov 24th

G LOWELL WEBB, M D

SIR,—I agree with Mr L. A. Parry (November 21st, p 977) that there may have been other reasons for trephining in ancient times besides depressed fracture. In a mediaeval Dutch oil painting a quack is shown as operating on the head of a dupe, and being surreptitiously supplied with stones (by a roguishly smiling boy) which the operator is professing to extract from the wound. The demand for such an operation must have been very considerable at that period to suggest such a painting. I had a patient who persistently demanded an operation for the removal of a growth, which he believed to be the source of a sensation referred to the vortex. The same sensations may possibly have been experienced by both mediæval and prehistoric men, with the same idea of obtaining relief.—I am, etc,

November 25th.

SENA

PREVENTION OF THE COMMON COLD

SIR,—I consider that the crux of the matter was stated by Dr Dobbie (BRITISH MEDICAL JOURNAL, November 14th, p 902) when she pointed out the great value of personal cleanliness.

The pocket-handkerchief is, in my opinion, the greatest cause of the spread and recurrence of the common cold. The handkerchief gets soaked, a clean one is not immediately available, so it gets rough-dried in front of a fire and so re-used unthinkingly over a prolonged period. In this way do we get reinfection.

For many years I have advised the sufferer from a "cold" to provide himself, at the onset of the disorder, with squares of common lint, small, but of useful size, which must be thrown on the fire and destroyed when used and soiled. On this being carried out with scrupulous care I have found a total absence of recurrences, and also a marked freedom from infection by other members of the sufferer's family.—I am, etc,

FORDS J STUART, M B, Ch B, D P H

Carnoustie N B, Nov 23rd

FOCAL INFECTION

SIR,—Dr Campbell Stark (BRITISH MEDICAL JOURNAL, November 21st, p 979) asks a question which one finds troubles many others. As he points out, the general practitioner frequently sees people with obvious "optic foci" enjoying good health, and others in whom no evidence

¹ The Art of Trephining among Prehistoric and Primitive Peoples. *Brit. Archaeol. Journ.* March 1916. Prehistoric Man and his Early Efforts to Combat Disease. *Lancet* June 13th 1914 and *Med. Press* July 8th and 15th 1914.

² and The Collective Evidence of Trephination of the Human Skull in Great Britain during Prehistoric Times. *Proc. Third Internat. Cong. Prehist. Hist.* Med. July 1922. The Prehistoric Trephined Skulls of Great Britain, etc. *Proc. Roy. Soc. Med.* vol. xiv, No 10 August 1921.

³ Trephination of the Living Human Skull in Prehistoric Times. *BRITISH JOUR. A* March 17th 1923.

of such can be found, although they are obviously suffering from some toxic absorption.

Frequently when asked to seek for the evidence of such foci in the chronically unwell patient one is able to verify what Wright and others have demonstrated—that it is not only the focus of infection or the infective organism that matters in any individual case, but rather the patient's tissue resistance to infective agents. One patient with a gall bladder full of pathogenic *B. typhosus* enjoys good health, while another, with a few comparatively mildly pathogenic *B. coli* in the pelvis of her kidney, is having rigors and every evidence of toxic infection.

Bacterial data alone are not always sufficient evidence, but such details lead in the light of cytological, serological, and biochemical blood findings will frequently indicate, not only whether the bacteriological data are of pathogenic importance to the case, but also which of the many isolated bacteria are particularly infective to the patient concerned. For instance, by thorough examination an asthmatic case may be found to depend upon an intestinal derangement or infectiveness as its main cause, while in a rheumatic case the infective focus is proved quite unexpectedly to be respiratory, in spite of suggestive dental, genito-urinary, or intestinal findings, while in many and varied clinical conditions the discovery of deficiency in essential gastro-intestinal function, with its train of subsequent metabolic derangements, will give the clue, not only to the hypersusceptibility of such cases to infection of low virulence, but also may suggest the means for effectively correcting the deficiency.

The apparently healthy people who are obviously displaying septic conditions have their good natural resistance to think for their immunity but they nevertheless carry a constant source of latent danger to themselves and others.

Health means that immunity to infection is greater than present infective risks. Ill health as regards infectiveness means the reverse, and the problem in regard to chronic focal infection is so to arrange by local, and more often general, means that the patient who has lost the knack of living happily with his germs should be helped to regain that gift—I am, etc.,

Southport Nov. 25th

E. CROFT LOWE

THE METHODS OF INVESTIGATION OF NEO-CARDIOLOGY

SIR,—I was much interested in the letter from Dr. Huntington Sunbury (November 28th, p. 1031). There is no doubt that a certain school of cardiology actually discourages the examination of the heart by auscultation and percussion, and places its faith almost entirely upon the deductions made from the polygraph or the electrocardiograph. Such teaching can only lead to disaster in many cases, and it encourages the idea that any medical man who installs an electrocardiograph in his consulting room is immediately converted into a heart specialist.

In my book upon *The Naheim Treatment* I stated my views upon this subject as follows:

There is a danger amongst a certain school of cardiologists to rely almost entirely upon the new methods of diagnosis and thereby to underestimate such valuable signs as the character of the heart sounds and the extent of the area of the cardiac dullness. If, however, this method is adopted it will lead neither to a complete diagnosis nor to a satisfactory treatment. To come to a true and accurate diagnosis in a case of cardiac trouble one must not only take advantage of the information obtainable from the newest and best scientific methods of investigation such as the polygraph and the sphygmomanometer but one must also make a careful study of the character of the cardiac sounds, the area of the cardiac dullness, and all other physical signs in any way connected with the heart and vessels.

—I am, etc.,

London W 1 Nov. 27th

LESLIE THORNE THORNE

NASAL PLASTIC REPAIR BY CARTILAGE GRAFT

SIR,—Permit me to congratulate Mr. E. Watson-Williams on his results with cartilage grafts in nasal plastic surgery (*BRITISH MEDICAL JOURNAL*, November 28th, p. 987). I can fully endorse his views of the excellence and simplicity of

this method, as I have been practising an identical procedure since 1916, the only difference in technique being that I insert a tenotomy knife in the central point, below the nasal tip, and extend the incision laterally to the extent required for the insertion of the cartilage graft. The preparation of the graft bed is also similar, but after the preliminary freeing by the tenotomy I use a small mastoid chisel, as being less likely to wound the skin than a knife and more likely to ensure a capacious gutter for the reception of the new cartilage, otherwise the latter may fit so tightly as to stretch the overlying skin and undesirable telangiectatic changes may result. For this reason also it is most important to make the graft bed in the subcutaneous tissues, leaving the whole true skin intact. Apart from continually placed deformities of the nasal ridge, cartilage grafts are also valuable, in a type so frequently seen in pugilists, in which the tip of the nose is depressed and the alae flattened out. The quadrilateral cartilage is broken and bent laterally into the nasal passages, causing obstruction to respiration, the columella end is sticking into one or the other nares, and owing to the absence of central support the nasal tip can be flattened out on the upper lip.

In all such cases, to relieve the nasal obstruction and restore the external contour of the nose, I resect the quadrilateral cartilage completely, except a small bowsprit above, and utilize a portion of what has been removed to implant in a columella gutter to raise the nasal tip. Another portion is inserted under the skin of the ridge as described above, the upper end of this graft resting on the nasal bones and the lower on the columella prop.

If this double implantation of cartilage is omitted the nasal tip remains depressed and the lateral alar cartilages collapsed, so that a simple resection of the septum will fail to relieve the nasal obstruction or the external deformity—I am, etc.,

London W 1, Nov. 27th

JOHN F. O'MALLEY, F.R.C.S.

ANAESTHETICS IN CHILDHOOD

SIR,—Dr. Primmer, in his criticism (November 28th, p. 1034) of Dr. Singleton's paper, states that he has "administered chloroform and chloroform alone" upon 2,310 occasions since 1900, that he considers it to be "the best of all anaesthetics", and that status lymphaticus does not exist.

Might I respectfully suggest to Dr. Primmer that he acquaint himself, both in theory and practice, with the various anaesthetics and apparatus in use at the present time before expressing a definite opinion on the subject? A perusal of the most recent literature would, I feel sure, convince him that his views are directly antagonistic to those of the leading authorities.

The adherents of the "chloroform school" have always held the view that the danger of chloroform lay in lack of knowledge of the drug's action and consequent faulty administration. From personal experience of 2,000 cases of "chloroform and chloroform alone" administered during 1920-22, and other anaesthetic agents since, I have been forced to the conclusion that chloroform, except as a supplementary agent to other anaesthetics at our disposal, does not justify its use.

Dr. Primmer would be well advised to obtain some experience with such apparatus as the Gwathmey warm nitrous oxide-oxygen inhaler and the Shipway ether-oxygen set, when, I trust, the thoughts of tombstones would, like chloroform, gradually pass into oblivion—I am, etc.,

Rotherham Nov. 30th

DOUGLAS C. SCOTLAND

SPIRITUAL HEALING

SIR,—There are to day a number of people who call themselves spiritual healers. Their slogan is "Believe in the Spirit and you will be cured. He will cure you where ordinary methods have failed." A great many people respond to this appeal, and when they are cured are loud in their protestations "I believed in the Spirit and I was cured." I would ask "What proof have we that the Deity directly intervened? Was it the Deity or the belief

1092 DEC 5, 1925]

CORRESPONDENCE.

in the Dory that cured?" It is my opinion that these cures are in fact the result of natural mental processes. How does the spiritual healer work? He says by appealing to the Spirit. I say by appealing to the mind. He asks the patient to believe in God and cure will follow. He appeals to the patient's belief. Belief is the real factor, and belief is an attribute of the mind. I have myself cured many diseases by getting the patients to believe in themselves alone. By telling them, "Your mind can cure you here, and it is only a question of shock, scintilla, the result of gunshot wound of the scintilla nerve, by fever, and insomnia, to mention only a few. And often the patient has said to me, "This is uncanny, supernatural, a miracle!"

There is a tendency to call that supernatural which we cannot understand. To-day we understand a good deal more than we used to about the natural forces of the mind, and many so-called supernatural cures can be proved to be the result of belief in the mind concerned. Most of us believe that man is possessed of a body, a mind, and a soul. There is abundant proof that the first two definitely exist. But, despite the hope inherent in most of us, I doubt if any educated man can produce proof of the existence of the soul as distinct from the mind. I do not wish to be misunderstood. I feel that belief in God and a life hereafter is a good thing for humanity helps many of us here below to bear the troubles and vicissitudes of this life. I so believe myself, and because it works for good I should be sorry to see such a belief brushed aside. But instead of realizing that we have got a would it not be more sensible for us, thank God for giving us mind which can do much for us, and belief is such a mind, and then develop it?

The basic factor in all these cures is belief, and belief is the patient to believe he will be cured, without any appeal to the spiritual side. If cure can be proved to be the result of an impression made on the mind alone, why complicate the situation by assuming the necessity for spiritual intervention? With respect I submit that all this talk of spiritual healing puts real religion in a false light amongst educated men. Cures effected by obviously mental forces are claimed as spiritual because they appear to be so wonderful.

Let us not forget that the spiritual healer makes his appeal through the mind of the patient concerned. Let us use the correct labels, and recognize that mental healing is a fact—spiritual healing not yet proven.—I am, etc.,
M P LEAHY
London, W1 Nov 24th

FOOD PRESERVATIVES AND DUODENAL ULCER

SIR,—The influence preservatives have upon digestion is so little appreciated that I feel impelled to report my own experience. The digestive troubles to which I became a martyr were ascribed to duodenal ulcer, but, by a process of exclusion, the malfactor has been definitely traced to preservatives. Prior to joining the army, at the age of 40, I had not experienced indigestion, and in the selection of food I merely consulted my desires. But a few weeks after enlistment digestive disturbances obtruded themselves and became so persistent that eventually I was compelled to report sick. My chief symptom was a dull pain in the epigastrium which, though worse a few hours after meals, was relieved by food. Rigidity of the overlying abdominal wall was present and tenderness could be elicited on deep pressure. Variations in the severity of the attacks were a feature, but dietary measures had no influence. After admission to hospital I was transferred to England for the operation of short circuit, the surgeons being convinced that I had a duodenal ulcer. Bismuth meals and chemical analyses of my gastric contents strengthened the diagnosis but as examination of the faeces never disclosed any haemorrhage I refused an operation. Two years later, at the conclusion of the armistice, I left the army a chronic dyspeptic, but I was resolved to give diet a thorough trial before submitting to surgical procedures.

At one time or another all kinds of dietetic measures were adopted, and though towards the end of each week I had a respite, the symptoms regularly recurred every Monday. Upon the advice of medical friends I renounced my habit of dining out on Sunday evenings, and supped at home, though the restaurants I had patronized were the most expensive of places and I ate but the simplest of food. At once my attacks were lessened, and by a gradual process of exclusion the symptoms were definitely traced to preservatives. The most indigestible of food now holds no terror, and, my tastes being epicurean, I persevere my private and rejoice in dinners my friends look upon as a crime, and cream containing preservatives, bought early, jam, or tinned food, an omelette or suco made from liquid eggs and cream for two days, a digestive week, wherever, when pure, the foods induce no symptoms. To demonstrate that the effect was not merely an obsession, I arranged at home that adulterated food should, unobtrusively, be served, and in every instance an attack followed.

Whatever the food, the symptoms are identical and consist of a dull pain localized to the epigastrium. The sensation is as if the deeper contents of the region were held in a tight grip, and, though it is difficult to portray in words an adequate description of the symptoms, the sensation is very distinctive and always of the same type. Beginning about twelve hours after adulterated food has been taken, the pain reaches its height in another day, it then gradually diminishes until at the end of the third day the serious have gone. Whilst food brings relief, the pain recurs about an hour after a meal, and though temporary relief is obtained from bismuth and other sedatives the attack always lasts about three days, whatever the treatment adopted. But if adulterated food be put down of only once every second or third day no intermission intervenes, and I again become a chronic dyspeptic. Pure food, however indigestible, never occasions an attack, but the simplest articles of diet, containing preservatives brings on the symptoms. And as the food of hotels and restaurants contains preservatives they are now beyond my patronage, and for the same reason I hazard no opinion, but the similarity of the symptoms is very suggestive, and I suspect that many cases labelled duodenal ulcer are merely the consequence of preservatives.

The addition of preservatives to food, by allowing of the marketing in this country of eatables garnered where the cost of production is low, has reduced prices. To an industrious nation cheap food is very desirable, but, however low the cost, the price is too high when part of the bill has to be met by indigestion.—I am, etc.,
JAMES TORRIST
London W1 Nov 7th

MALARIAL TREATMENT

SIR,—In connexion with the malaria treatment of general paralysis I find *Mercure de France*, May 15th, 1925, P 197, according to Dr Cabanes, that in the Middle Ages it was believed that quinine cured epilepsy. He quotes Louis XI as begging the Prior of Notre-Dame de Salles, at Bonnes, to pray "incessamment Dieu et Notre-Dame de Salles pour moy, car j'ay une maladie dont do m'enoyer la fièvre quarte, car j'ay une guery sans Pavyon." les physicians disent que je ne puis estre guery sans Pavyon. Cabanes states that Louis XI was an epileptic. More over, it appears he also suffered from leprosy. This throws a good deal of light on the King's strange behaviour, though notwithstanding such drawbacks he managed to weld a disunited country into a kingdom.—I am, etc.,
GEORGE PENNY

Obituary

SIR CHARLES BROWN, M A, M B, F R C P, F R C S,
Consulting Medical Officer, Preston Royal Infirmary

We announced briefly last week the death, on November 23rd, of Sir Charles Brown of Preston, a veteran member of our profession, and a munificent friend to medical research and medical charities.

Robert Charles Brown was born on October 2nd, 1836, in the house in Winkley Square, Preston, where he died. His father was Alderman Robert Brown, F R C S, for thirty-five years a leading practitioner in that town and the country district around it. On leaving Preston Grammar School, at the age of 17, Charles Brown became a pupil of his father's colleague, Thomas Dixon, and in 1855 entered as a medical student at King's College, London. He obtained the diplomas of M R C S Eng and L S A in 1858, graduated M B Lond in 1861, and in the following year passed the examination for the Fellowship of the Royal College of Surgeons of England. In 1865 he became M R C P Lond, and many years later, in 1908, the Royal College of Physicians honoured him by election into its Fellowship.

The death of his father in 1858, shortly before he had obtained his first qualifications, compelled him to earn his own living without delay, and he became house surgeon to the old Preston Dispensary, he held that post, with intervals of study in London, Edinburgh, and Dublin for higher examinations, until 1863, when he began private practice and was appointed an honorary medical officer to the dispensary. When the Preston and County of Lancashire Royal Infirmary was opened in 1870 he was transferred to the staff of that institution and identified himself with its fortunes, he had long been the only survivor of the original members of its medical staff. During his many years of practice in Preston he held a number of appointments outside the infirmary, including those of certifying factory surgeon, medical officer to the Lancashire County Constabulary, local medical officer for fifty years to the London and North-Western and Lancashire and Yorkshire Railway Companies, and consulting medical officer to the local orphanage and deaf and dumb school. In the sixties he held a commission as assistant surgeon to the 3rd Royal Lancashire Militia.

He often had it in mind to proceed to the M D degree and worked hard in preparing for it, once when he was 27 and again at the age of 64. On the first occasion he failed in logic and moral philosophy, then obligatory subjects, on the second, although I had put down my name and paid the fee, I took flight and returned to Preston two days before the examination commenced, intending to go up in 1901, but I could never muster courage to do so. He consoled himself, however, for this "stupidity" by recalling in after years the distinctions he had received from other

sources. These were the Associateship of King's College, London, the office of Esquire in the Order of St John of Jerusalem, Fellowship of the Royal College of Physicians, freedom of the Borough of Preston (conferred in recognition of his professional services and munificence to the Royal Infirmary and other institutions), an honorary degree at Cambridge, and the knighthood conferred in 1919. Another cause for legitimate pride was the honour paid him by his local colleagues in thrice electing him president of the Lancashire and Cheshire Branch of the British Medical Association, and re-electing him chairman of the Preston Division for thirteen years in succession. He became a member as long ago as 1859, and continued in membership after his retirement from active work. In 1902, when the Association met in Manchester, he was vice-president of the Section of Medicine.

Beyond many benefactions to the town of his birth, Sir Charles Brown was ever ready to help in what he felt to be good causes elsewhere. One instance was his generous support of the Cambridge Research Hospital. From the first he had been intimately concerned in the work of the Cambridge Committee for the Study of Special Diseases, and his personal services to the hospital established by that committee in Hill's Road, Cambridge, under the direction of Dr Strange ways, were unemitting. Besides a very complete x-ray installation, he provided a microphotographic apparatus of the latest type, and founded a studentship for pathological research. It was in recognition of these gifts that the University of Cambridge, on May 23rd, 1912, conferred on him the degree of Master of Arts, *honoris causa*. The Public Orator, in presenting him for the degree, aptly described him as "mediocris modestum, medicum munificum." This honour from the University of which his two brothers were members gave him particular pleasure. On the following day the newly built Research Hospital was opened by him in the presence of a distinguished assembly of nearly five hundred people. After speaking

[Hills and Saunders Cambridge]

SIR CHARLES BROWN, HON. M A CANTAB

with pride of the progress in the field of medicine which he had been privileged to see in his own lifetime, he said:

"The future depends on research, and research into special diseases is not only important in itself for those diseases, but may throw new light and open new vistas everywhere."

The honours that came to him were felt by his colleagues to be thoroughly well deserved, for no man better earned the esteem and affectionate regard of friends within and without the profession. His influence though quiet and modest was wide, and was always exerted for the betterment of medicine and the maintenance of a high standard of professional conduct. His mind continued active up to the last, and from time to time little notes on invalid and kindred matters would come to us from his bedside in Preston. At the age of 86 he published his reminiscences under the title *Sixty-four Years a Doctor*. In this he briefly outlined his own career, covering a most interesting period of national and local history and reviewed some of the social

phases he had passed through, with special reference to the immenso advances made during this period in medical science and practice. Characteristically he gave the profits from this unpunctuated book to the hospital with which he had been connected since its foundation. He dedicated it, "with a feeling of the most profound respect and admiration," to Sir Clifford Allbutt, who also was born in 1836 and died in 1925, and often corresponded with him in later years on research and other matters new to both their hearts.

Sir Charles Brown was an ardent musician and a firm believer in the therapeutic value of music. As a boy he saw the disappearance of the old stage-coach, and for the rest of his life he took the greatest interest in railways and everything associated with them. He never married.

Dr T S P STRANDEWYK, Lecturer in Special Pathology, University of Cambridge, and Director of the Cambridge Research Hospital, writes:

I appreciate the privilege of being allowed to express my feelings of high admiration and respect for the late Sir Robert Charles Brown, and of acknowledging my deep personal gratitude for his never-flagging interest in the Cambridge Research Hospital and his generosity to it. It was my good fortune to know him intimately for many years, and I always greatly enjoyed my visits to 27, Winkley Square. All those who have experienced his delightful hospitality must recall after-dinner chats full of reminiscences of his student days and early life, and the pleasure with which he entertained them with his simple recitals on his organ. Many will doubtless remember being awakened in the early morning by the dissonant notes of the same instrument. Of his generosity to Preston Infirmary and other charities I need not speak, but I must pay my tribute to the great help and encouragement I received from him ever since the Cambridge Research Hospital was founded. In the early days, when encouragement was most needed, he never refused any request for help I made to him. He showed a great interest in all medical research, and the following extract from his will shows how deep this interest was:

"I bequeath my body to the Directors of the Research Hospital Cambridge, and authorize them to retain such parts of it as they consider may be suitable additions to their Pathological Museum."

He was a simple, kindly, generous soul, full of love for his fellow beings, and he will be greatly missed by his many friends.

Dr F W COLLINSON, Honorary Consulting Surgeon, Preston Royal Infirmary, writes:

The general public, and especially the medical profession, of Preston and neighbourhood will feel the great loss of Sir Charles Brown. He lived in the town all his long life. He was greatly esteemed by us all, and many members of his profession are indebted to him for the encouragement and help he gave them in their early practice. He was untiring in his industry and perseverance, and his instinctive tact and power of sympathy endeared him to all. An optimistic outlook upon life was natural to him. His self-discipline and denial, which arose from a religious conviction, was greatly to be admired. His association with the Preston Royal Infirmary dated from its inception. He assisted in the collection of money for the erection of the original building, and was on the staff from the time the infirmary was opened in 1870 to his death, first as house-surgeon, then as honorary physician, and for a number of years, as consulting physician. The institution has received numerous benefactions at his hands. After inspecting various operating theatres, he built, entirely at his own expense, a most up-to-date operating theatre, with all the necessary appointments. He also provided isolation wards, conservatories, and many other things for the comfort and welfare of the patients. When a rays was first introduced he defrayed the cost of an outfit, which was the best at that time. From the year 1889 to the date of his death his gifts to the infirmary amounted to more than £10,000. His great benevolence also showed itself in many other charitable organizations

in the town. The Preston Town Council in September, 1910, conferred upon him the great honour of the freedom of the borough.

All his life he found great joy in music, and for many years was honorary organist at one of the town's churches. The operas of Gilbert and Sullivan afforded him great delight, and many of the nights performing at the theatres were hospitably entertained by him. He was a man of simple tastes, and had no desire to spend money upon himself, but frequently denied himself that he might have more to bestow on others. In his later years he often said he found the value of money now that he was giving it away. Although from physical disabilities he was unable to go out, except rarely in a bath chair, during the last two or three years, his mental powers remained singularly available. He had an almost uncanny memory, and up to his last illness his ability to memorize new data was astonishing. He always took a keen interest in the progress of his profession, and often delighted in recounting the amazing improvements, in surgery especially, whereby such great relief could be given. Happily, his illness was a very brief one, lasting only a fortnight, and he passed peacefully away.

CAROLINE KEITH, L.R.C.P. and S.E.D.,

Formerly Anaesthetist to the Chelsea Hospital for Women and to the New Hospital for Women

On Tuesday, November 24th, died at Southsea Dr Caroline Keith, one of the most loyal colleagues and conscientious practitioners among the long list of women who have qualified from the London (Royal Free Hospital) School of Medicine for Women.

She was appointed anaesthetist to the New Hospital for Women some thirty-five years ago, about the same time that Mrs Garrett Anderson's influence made me surgeon there. From that time until I went to the Royal Free Hospital in 1902, Mrs Keith, Mrs Stanley Bord, and I were very happy colleagues. In moments of emergency and trial the surgeon's greatest support and comfort is in the reliability and skill of the anaesthetist and of the chief assistant. Both my friends have obtained promotion, and I am thankful to be able once more to record my deep indebtedness to them.

Caroline Keith was a curious mixture of French and English characteristics. She came of an Alsatian family and was French to the backbone in all that concerned her country and its fortunes, but she married Surgeon Captain Keith when she was very young and as yet knew no English. In after-years she used to dwell with her delightful sense of humour on the strange courtship between the reticent Scottish man who knew no French and the impulsive French maiden who knew no variety of English. The time came when the medical officer had to leave his young wife for service up-country in India. She had by this time acquired some English, and he entreated her to enter the London School of Medicine for Women and to qualify, thinking thereby to secure both her happiness and her independence in case of need.

Caroline Keith was very successful in the exercise of her profession. She chiefly excelled in anaesthetics and obstetrics, and in these capacities she is still held in grateful remembrance by colleagues and pupils, patients and friends. For many years Mrs Keith was anaesthetist to the Chelsea Hospital for Women, and was a real friend and much appreciated colleague to the medical men for whom she worked.

It was thoroughly characteristic of my old friend that when she had saved enough to bear her share of house-keeping expenses she resolutely retired, and no prospect of riches, no love of professional work, sufficed to keep her in harness when she felt that she deserved freedom and leisure. Consequently she retired many years ago in the very prime of life and when her professional usefulness was at its height.

After the death of her husband Mrs Keith spent much of her time with her son and his wife in India, paying occasional visits home and maintaining in all their freshness her old and valued friendships. She lived much beloved, and she died greatly regretted.

MARY SCHAPLIER

- DECIMUS CURME, M R C S, L S A,
LIEUT COLONEL R A M C, T F,
Child Okeford

LIEUT-COLONEL DECIMUS CURME, R A M C, T F (ret), of Child Okeford, Blandford, Dorset, died at Bournemouth on November 25th, aged 86. He was educated at King's College Hospital and at Paris, and took the M R C S and L S A in 1861. He served for some years as surgeon superintendent in the Chinese Emigration Service, and was afterwards in practice in Chester, where he was visiting surgeon of the Chester General Infirmary, but more than half a century ago settled at Child Okeford, where he was medical officer and public vaccinator of the Child Okeford district of Sturminster Union.

He joined the Dorsetshire Militia as assistant surgeon in the sixties of last century, and retired as surgeon lieutenant-colonel of the third battalion (militia) of the Dorsetshire Regiment. He served in the South African war of 1899-1902, taking part in operations in Natal, including the relief of Ladysmith, and the action of Tugela Heights, in the Transvaal, and in Cape Colony, and received the Queen's medal with four clasps and the King's medal with two clasps.

He joined the British Medical Association in 1877, he was Vice-President of the Dorset and West Hants Branch in 1889 and President in 1899. He was a member of the Branch Council in 1906-7, 1911, and from 1915 to 1921, and for fifteen years was the representative of the West Dorset Division on the Representative Body. He was also a member of the Naval and Military Committee, 1904-9.

The death occurred suddenly, on November 24th, of Dr CHARLES EDWARD LANSDOWN, a well known practitioner in Cheltenham and district. He was a native of Plymouth, and was educated at St Mary's Hospital Medical School, Paddington, where he won a science scholarship. After taking the diplomas of the English Conjoint Board in 1891 he served as house-surgeon to St Mary's Hospital, resident medical officer to the Horton Infirmary, Brimbury, and senior resident medical officer to the London Lock Hospital. He subsequently began practice at Cheltenham, and was appointed surgeon to the Children's Hospital, Cheltenham. Dr Lansdown had practised in Cheltenham for more than a quarter of a century, and was for many years a member of the Gloucestershire Branch of the British Medical Association. During the war he was one of the medical officers in charge of the New Court Red Cross Hospital, and he received the O B E decoration in 1920. He was a very keen Freemason, and for some years was churchwarden in the parish of St John's. He leaves a widow, one daughter, and two sons.

Dr JAMES FULTON MUIR of Whitehaven died suddenly from heart failure on November 15th, aged 67. He was a native of Glasgow, and was educated at Glasgow University, where he graduated M B, C M in 1880, and M D in 1892. After serving as house surgeon to the Royal Infirmary, Glasgow, and to the Dumfries and Galloway Royal Infirmary he became assistant to the late Dr Bateman Wilson of Whitehaven, and subsequently commenced practice there on his own account. From 1886 to 1905 he was a member of the honorary surgical staff of the Whitehaven and West Cumberland Infirmary. He also held the appointment of certifying factory surgeon. Dr Muir was a prominent Freemason, and was for some years president of the Whitehaven Burns Club. He was a member of the English Division of the Border Counties Branch of the British Medical Association.

Professor PAUL HEGER, honorary president of the free University of Brussels and formerly president of the Belgian Royal Academy of Medicine, has recently died at Brussels at the age of 76. His father, Professor Constantin Heger, was the friend and instructor of Charlotte Brontë.

Professor J GUTERAS Y GENSER, professor of general pathology and tropical diseases in the University of Havana, president of the Cuban National Board of Health, and founder of the *Revista de medicina tropical*, has recently died.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE House of Commons has this week taken the concluding stages of the Rating and Valuation Bill, discussed the recent prosecutions of Communists, and considered resolutions proposed by the Government for duties on leather and fabric gloves, gas mantles, packing paper, and certain kinds of cutlery, including knives other than surgical knives, scissors, and razors, including safety razors. The duties are proposed for a term of five years, and those on cutlery are at 33½ per cent *ad valorem*.

On December 1st the Home Secretary introduced without exposition a Coroners (Amendment) Bill. This is described as non-controversial, but the Government has little hope of getting it through this session.

Dr Salter, on the same day, presented a Public Health (Smoke Abatement) Bill. This cannot be debated the Government has taken all the time of the House, but the Ministry of Health hopes to deal with the subject next session.

In the House of Lords, on December 1st, the Public Health (Scotland) Bill, which will enable local authorities to supply insulin free to certain classes of persons not at present entitled to it, was read a second time after a short discussion. The third stage was also taken. The bill has already passed through the House of Commons.

The Medical Committee of the House of Commons will meet early next week, and proposes to discuss informally the constitution and powers of the General Medical Council. This discussion was not arranged as a result of recent disciplinary action by the Council.

Colonial Medical Director—On November 30th Lieut Colonel Angus McDonnell asked the Colonial Secretary whether the Government had come to any decision as to the appointment of a medical director as a permanent member of the Colonial Office staff for the purpose of co-ordinating medical research work in the different Crown Colonies. Mr Amery said that the matter was still under consideration.

Increase of Beds in Voluntary Hospitals—In reply to Major Glyn, Mr Neville Chamberlain said he had considered the report of the Voluntary Hospitals Committee. While he appreciated the strength of the case for additional beds he regretted that in the present urgent need for public economy he could not recommend the provision of public funds even for so laudable an object.

Vaccination—On November 26th Mr Groves asked the Minister of Health whether he was aware that, in circumstances where adults were persuaded to be vaccinated or revaccinated and unexpected results ensued necessitating abstention from work, no provision was made for compensation for loss of wages other than the national health insurance scheme and whether as many workers were not covered by such scheme he would consider a scheme for compensation in the cases referred to. Mr Neville Chamberlain said that as regarded the first part of the question there was no statutory provision for the payment of compensation for loss of wages in the circumstances mentioned. As regarded the second part he did not think it necessary as at present advised to consider any general scheme for compensation in such cases. Mr Groves further asked the Minister of Health whether he was aware that many private medical practitioners still employed the arm to arm method of vaccination and whether in view of the serious risks attending such practice, he would consider the desirability of making representation to the medical profession on the matter. Mr Neville Chamberlain said that the answer to the first part of the question was in the negative. His information was that comparatively few medical practitioners now employed this method and he scarcely thought it necessary to make representations to the medical profession on the matter. Mr Neville Chamberlain said he would consider in connection with other questions relating to sleep sickness which were at present engaging his attention the suggestion that he should give instructions to all medical officers to inquire whether cases of sleep sickness had at any time undergone vaccination and if so to note the date and the result of the last vaccination.

Small pox—On November 26th Mr Groves asked the Minister of Health whether he could present statistics showing the total number of small pox cases notified by the various boroughs and urban districts from 1891 to 1924 and the percentage of births vaccinated for each of these years. Mr Neville Chamberlain said that statistics showing the total number of small pox cases notified in the various boroughs and urban districts in England and Wales would be found in the annual volumes of Statistics of the Incidence of Notifiable Infectious Diseases in each Sanitary District in England and Wales which were published by the Local Government Board and the Ministry of Health for the years 1911 to 1920 and in the Registrar General's statistical review for the years 1921 onwards. Similar statistics were not available for the years prior to 1911, nor were figures as to the percentage of births vaccinated in boroughs or urban districts.

Medical Attendance on Families Army and Air Force—In answer to Mr. H. Morrison, Mr. Bridgeman (First Lord of the Admiralty) said that wives and families of officers and men of the Army and Royal Air Force were entitled to receive treatment as outpatients at Royal Naval hospitals at home and abroad, if they were entitled to treatment under existing regulations from their own medical officers and if treatment by those officers was not readily and conveniently available. Asked further whether he would consider the desirability of equality of treatment of the wives and families of officers and men in the three services, Mr. Bridgeman said the Admiralty was satisfied that, owing to the varying conditions of the services, a complete assimilation of the conditions and regulations governing medical treatment in the services would not be desirable.

Health of Merchant Seamen—On November 24th Mr. B. Smith asked the President of the Board of Trade whether he would arrange for an annual report to be issued regarding the health of merchant seamen, giving a scientific analysis of diseases in the statistics published in the return of the shipping casualties to and deaths on vessels registered in the United Kingdom, giving information as to the total number of men serving amongst whom the deaths occurred and in view of the apparent absence of medical advisers in the department, if he would consider whether the health of seamen was a responsibility which might with advantage be transferred to the Ministry of Health. Sir Philip Cunliffe-Lyster said he would consider whether the statistics for which the hon. member asked could be prepared.

Lead Poisoning—Answering Mr. Duckworth, Mr. G. Locker-Lampson (Under Secretary Home Office) said there had been a small increase during the last few years in the deaths from lead poisoning in the pottery trade, but this could not be taken as any indication of present conditions. In the great majority of cases the deceased had been employed in the industry for many years before the regulations of 1913 came into force. There could be no doubt that these regulations had been effective. In the fatal cases there had been a substantial rise in the average age of the deceased, and the statement that potters between 35 and 45 had the highest death rate in Great Britain was, he believed, incorrect.

The Spallinger Treatment—On November 30th Captain Bowyer asked what steps the Minister of Agriculture was taking to test M. Spallinger's reputed cure for bovine and human tuberculosis or whether the Ministry was already satisfied as to the efficacy of M. Spallinger's serum. Sir H. Barnston said that the Ministry had not itself made any test of M. Spallinger's serum, or of any other specific of which the basis was kept secret and not submitted to scientific inquiry. It understood however that an investigation into bovine tuberculosis was being undertaken by a committee representative of certain agricultural and professional interests in Cheshire, where tests were being conducted with the co-operation of M. Spallinger. It was intimated that the matter would be raised on the adjournment of the House at the first available opportunity.

Experiments on Animals—Commander Kenworthy asked the Home Secretary how many of the 177,815 experiments on animals reported by the Home Office as having been performed during the year 1924 were actually witnessed by the inspectors appointed for that purpose where such experiments took place, and under what certificate or certificates those experiments were performed, or if under licence alone. The Home Secretary replied that all the places at which experiments were permitted were visited frequently by the inspectors during the year and the animals under experiment at the time of the visit were inspected, but he could not give the number of these animals. The great majority of the experiments were continuing experiments—for example, the inoculation experiments on the experiments under Certificate B in which the animal was kept alive after the initial operation under anaesthesia had been carried out. If the question was intended to refer to the return operative procedures witnessed the answer was: Experiments witnessed in 1924—327 performed under licence alone 18 under Certificate A 302, under Certificate B 6 under Certificates B and LL 1.

Secret Remedies—Mr. Neville Chamberlain informed Sir John Marriott that he had not received any recent representations urging him to introduce legislation to deal with advertisements for cancer cures but the matter had been fully discussed in the report of the Select Committee on Patent Medicines. Asked further as to what action it was proposed to take Mr. Chamberlain said the question would be carefully considered in connexion with any legislation for the control of the traffic in secret remedies.

Red Crescent and the Riffs—Mr. Austen Chamberlain stated, on November 24th that no formal application by the Red Crescent Society for permission to transmit medical necessities to the Riffs had been received but certain private persons had made inquiries on the society's behalf. They had been informed that the French and Spanish Governments were alone competent to sanction the importation of medical stores into the Rif, and that application should be made to these Governments.

Notes in Brief

There were nine deaths from insect bites in Great Britain during the six months ended September 30th 1920. The corresponding figure for 1925 is not available.

The Home Secretary considers that legislation prohibiting the sale of inflammable toys would be impracticable.

The Ministry of Health is working with the Ministry of Agriculture for improvement in the conditions of hop-pickers' camps, and is circulating a report by a medical officer of the Ministry on hopfields in Kent and Sussex.

A draft Milk and Dairies Order under the Act of 1915 will be ready for publication about the end of the year.

The Departmental Committee on Child Assault hopes to publish its report early this month.

In consequence of the recommendations of the committee appointed to consider the employment of pharmacists in the army an army school of dispensing has been established and a reserve of pharmacists for war formed, it is not proposed to take any further action.

The special treatment of insured persons for rheumatism will be considered after the report of the Royal Commission has been received.

Universities and Colleges

UNIVERSITY OF OXFORD

Convocation has approved the appointment of Dr. P. N. B. Odgers of Lincoln College as Demonstrator in the Department of Anatomy.

The appointment of Dr. E. W. Ainley Waller Fellow of University College, as University Lecturer in Pathology has been renewed for a further period of five years.

UNIVERSITY OF CAMBRIDGE

The Raymond Horton Smith Prize for the best M.D. thesis submitted during the past academic year has been awarded jointly to J. H. Barn of Emmanuel and G. A. Harrison of Gonville and Caius whose theses are adjudged of equal merit.

At a congregation held on November 28th the following medical degrees were conferred:

M.B. B.Chir.—V. W. Dix, J. H. T. Davies, B. D. Hendy.
M.B.—J. L. D. Crozier, P. N. D. Hart.

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

DIPLOMA IN PSYCHOLOGICAL MEDICINE (with special knowledge of Psychiatry)—E. W. Anderson, G. Brown.

The degree of D.Sc. (Entomology) has been awarded to Henry Pollard Jaeger, M.D., of the London School of Hygiene and Tropical Medicine.

Medico-Legal.

AN OVERLOOKED SWAB

IN the course of an inquest at the Manchester City Coroner's Court, on November 27th, concerning the death of Miss Florence Halkyard, aged 29, an allegation was made that a swab had been left in the woman's body after one operation and had been found in the body during a further operation. A verdict of "Death from misadventure" was returned.

It appeared that the deceased entered St. Mary's Hospital, Manchester, on July 11th 1925 as a private patient. She was operated upon and returned to her home, where she was confined to her bed for nine weeks. Upon readmission to the hospital a further operation was performed in the course of which a swab was found to have been left in the body after the first operation. An abscess had set up, and death ensued from peritonitis.

A sister at the hospital said she was present when the first operation was performed. The method followed at operations was to serve out swabs in packets of ten, one packet being used at each operation. The number was checked at the beginning, checked again at the conclusion and signed for in a special book. This process was followed at the first operation on the deceased and she signed for ten swabs at its conclusion. She could not account for the swab since found in the body of the deceased. Another sister at the hospital said she made up the packets of swabs the day before the operations. In reply to Mr. Judson (representing the husband), she agreed that there might have been eleven swabs in the packet.

Dr. Hunter, resident obstetric surgeon at St. Mary's Hospital, stated that he assisted Dr. Bude at the first operation. A most careful examination was made at the close, and there was no sign of any swab having been left in the patient's body. He was present at the second operation when the swab was found. There was an abscess in the abdomen and in the centre was a swab, presumably left at the first operation. The deceased's husband was informed of the fact.

In answer to the coroner Dr. Hunter said that the ultimate cause of death was peritonitis.

The coroner (Mr. C. W. W. Surridge) in returning a verdict of "Death from misadventure" said there was no doubt as to the cause of death. At the same time, the publication of this case might cause a wrong impression in people's minds. Operations were constantly being performed in hospitals and patients were

restored to health. This was one of those cases when a person became accustomed to performing a certain duty a great many times and occasionally a mistake occurred. So far as his recollection went he had never had an unfortunate occurrence of this kind before. He was quite satisfied that nothing in the nature of criminal negligence had taken place. The hospital regulations were such as would be expected in an institution of that character and he was certain that in any inquiry they might make anything they decided to do that would still further ensure safety from any possible mistake would be done. One further objection he would like to make, and it was that everybody concerned had been perfectly frank. There had been no attempt to shelter anybody in what had been an unfortunate mistake.

Mr James Fox expressed the deepest sympathy with everybody connected with St Mary's Hospital at what had occurred.

Medical News.

THE meeting of the Society of Medical Officers of Health at the Medical Institute Newcastle on Tyne, will be held on Friday next, December 11th, and not on the date previously announced. The President (Dr G F Buchanan) will be in the chair, and there will be a discussion on "Industrial Hygiene" from the point of view of Public Health Administration (Professor Harold Kerr, M.O.H. Newcastle on Tyne), the Physician (Sir Thomas Oliver, M.D., F.R.C.P.), the Works Director (Mr Angus Watson, chairman of Messrs Angus Watson and Co.), and the Welfare Supervisor (Mr B L Lelchott, welfare supervisor, Messrs Sir James Laing and Sons, Sunderland). The dinner of the Northern Branch will be held at the close of the meeting, and members of other branches are invited to notify Professor H Kerr, Town Hall, Newcastle on Tyne if they are able to attend. As branches have often expressed the wish that meetings of the whole society should be held from time to time in the provinces, it is hoped that there will be a large attendance, especially of members from the North of England and Scotland, at the Newcastle meeting.

PROFESSOR J C G LEDINGHAM, F.R.S., will give the Huxley Lectures of the Royal Institute of Public Health next week. The subject chosen is current problems in bacteriology and immunology, and their bearing on public health effort. The lectures will be given at the house of the Institute (37, Russell Square, London, W.C.1) on December 9th, 10th, and 11th, at 5 p.m.

SIR C GORDON WATSON will lecture for the Fellowship of Medicine on the prevention and correction of deformity in tuberculous joints in the lecture hall of the Medical Society of London, 11, Chandos Street, W., on December 7th at 5.30 p.m. The lecture is free to members of the medical profession. The Hampstead General Hospital will hold a late afternoon course from December 7th to 19th, covering all branches of medicine and surgery. On December 7th also a two weeks' afternoon course in dermatology begins at the Hospital for Diseases of the Skin, Blackfriars, in which will be given in the out-patient department, and venereal clinics will be held twice weekly. The following special courses for January are announced: medicine, surgery, and the specialties at the Prince of Wales's General Hospital, cardiology at the National Hospital for Diseases of the Heart, diseases of children at the Queen's Hospital, infectious fevers at the North Eastern Hospital, neurology at the West End Hospital for Nervous Diseases and psychological medicine at the Bethlem Royal Hospital. A copy of each syllabus and the Fellowship general course programme may be had from the Secretary, 1, Wimpole Street, W.1.

On December 11th Dr Otto May will lecture before the Tuberculosis Society on his assurance and tuberculosis. Professor Lytle Cummings will address the January meeting on clinical types of pulmonary tuberculosis in Wales, and Dr C Nicory will speak in February on tuberculosis in Japan. The provincial meeting will be held from March 25th to 27th at Cambridge in conjunction with the Society of Medical Superintendents of Tuberculosis Institutions.

A FURTHER series of lectures will be given by the medical staff at Queen Charlotte's Maternity Hospital, Marylebone Road, N.W.1, on Thursdays, at 5 p.m., commencing January 14th, 1926 when Mr A W Bonine will speak on maternal mortality. On January 21st Mr J Bright Banister will deal with late manifestations of puerperal sepsis. The other lectures in the series to be given on successive Thursdays include addresses by Mr T B Davies on ante partum hemorrhage, Mr L C Rivett on infant feeding, Mr L G Phillips on management of contracted pelvis, Mr C S Lane Roberts on ectopic pregnancy and Mr L H W Williams on acute abdominal pain in pregnancy.

THE next meetings of the Royal Commission on Lunacy and Mental Disorder will be held at 5 Old Palace Yard, on December 10th at 2 p.m. and December 11th at 10.30 a.m.

THE annual general meeting of the Old Epsomian Club will be held on Thursday next, December 10th, at 6.30 p.m., at the Trocadero Restaurant, London. It will be followed by the annual dinner at 7.30.

WE regret to record the death of Mr R G Blackall, an early worker with x-rays at the London Hospital. He had been suffering from x-ray dermatitis for many years and epithelioma developed, necessitating the amputation of both his hands. He retired in 1920, after eighteen years' service at the hospital, and went to live at Leigh-on-Sea. The Cringle Hero Fund Trustees awarded him in December, 1923, a certificate of honour and a grant of £75 a year. In the following March Lord Kintford presented the framed testimonial of the Hero Fund to him, and announced that the London Hospital had awarded him a pension of £285 a year and was insuring his life for a substantial sum on behalf of his wife and family.

WE are asked to state that the Wellcome Historical Medical Museum was closed on December 1st and will not be reopened until the end of May. The growth of the collection has been so great that extensive alterations have become necessary. Communications should be addressed to the Secretary of the Museum, 54A, Wigmore Street, London, W.1.

THE KING has confirmed the appointment of Dr Ernest Shawe Corse, Chief Medical Officer, Cyprus, to be nominated as an official member of the Legislative Council of Cyprus.

WE have received the first issue, which appeared in October, of *Archivos Argentinos de enfermedades del aparato digestivo y de la Nutricion*, a bi-monthly journal dealing with alimentary diseases and published at Buenos Aires under the editorship of Professor Carlos Bonorino Udaondo. The issue contains original articles by Pierre Duval and J C Ronx on congenital peridnadenitis, by C B Udrondo, J L Cynlla, and H Zunino on basal metabolism in cancer of the stomach, by M R Castex and J C Galan on guardians of the bile ducts, by Delfor del Valle on duodenal ulcer, by P Escudero and E U Merlo on retractile mesenteritis, by T Martini on essential stenosing peridnadenitis, and by M R Castex, N Romano, and J J Beretervide on insufficiency of the ilio caecal valve, a review of the subject of infected gastric or duodenal ulcer, by A Ceballos, and abstracts from current literature.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, **British Medical Association House, Tavistock Square, W.C.1** on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL** should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the **British Medical Association** and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9561, 9562, 9563**, and **9564** (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are **EDITOR OF THE BRITISH MEDICAL JOURNAL, Antology Westcent London**.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) **Antology Westcent London**.

MEDICAL SECRETARY, Westcent London.

The address of the Irish Office of the **British Medical Association** is 16 South Frederick Street, Dublin (telegrams **Bacillus Dublin** telephone 4737 Dublin) and of the Scottish Office 6 Drumsburgh Gardens, Edinburgh (telegrams **Associate Edinburgh** telephone 4361 Central).

QUERIES AND ANSWERS

BAGGY EYELIDS

MR. BISHOP HANMAN (London) writes in reply to the inquiry of J G B (November 28th p 1039) as to the pathology of "baggy" eyelids met with in apparently healthy individuals of middle age. The limitation to the healthy excludes puffiness due to renal disease, myxoedema, angio-neurotic oedema, and local inflammatory changes. The ordinary baggy eyelids are not pathological but a feature of the physiognomy of certain types. They occur mostly in those who in youth possessed fine prominent eyes, in which the absorption of orbital fat and connective tissue of the lids renders the skin of the lids

redundant These persons are very liable to suffer from entropion after an attack of conjunctivitis The treatment where the deformity is serious is the same as that for entropion A slip of skin of the biggy lid about 4 mm wide and 15 mm long is excised parallel to the lid border and about 5 mm below it A corresponding strip of the underlying orbicularis palpebrarum is excised Then the cut edges of skin and muscle and the deeper connective tissue are included in sutures Three or four fine horsehair sutures suffice It is essential that the skin and muscle should be sewn to the deeper tissue The operation may be done under local anaesthesia The wound heals in three days, when the stitches are removed The scar cannot be seen at the end of one month The results are excellent and permanent Warning may be given that such cases are sometimes treated by 'beauty specialists' with paraffin wax injections I have seen most unfortunate consequences

INTERMITTENT CLAUDICATION

M D " asks for information about this condition, of which he is a victim He is 65 years of age and has always been of active habits His activities however have been gradually restricted during the last six years owing to dyspnoea on effort and a ginal pain in the precordial region on slight exercise About two years ago, while walking, he was suddenly seized with sharp pain in the right calf This was quickly relieved by rest—that is to say, by standing for a minute or two—but it was apt to recur when he resumed his walking Later the pain in the calf muscles became a constant and troublesome hindrance to locomotion, the muscle mass was very tender, and massage seemed to do good It was suggested to him that the condition might be intermittent claudication, due to arterial spasm, or possibly to arteritis he therefore had the blood pressures taken at different levels of the legs, with the following results

Right Leg			Left Leg		
	Max	Min		Max	Min
Thigh	200 mm	90 mm	Thigh	200 mm	70 mm
Just below knee	190	90	Just below knee	190	70
Ankle	120	90	Ankle	170	70

The pressure in the arm was at that time maximum 150 mm, minimum 90 mm The drop of the pressure in the right leg towards the lower part is very striking (this was measured with a Fauchon instrument) Our correspondent is inclined to attribute the pain to arterial spasm and not to structural changes The leg has not been radiographed to see whether there is any arterial calcification Three or four months ago, when tying his bootlace at an inconvenient angle something seemed to give way with a sharp pain on the inner side of the right ankle, which became slightly distended with fluid and rendered walking uncomfortable The whole leg became subsequently oedematous, especially over the lower third readily pitting on finger pressure Over the inner aspect of the lower fourth of the tibia there was a fluctuating swelling, which was not painful or tender although there was at times obscure smarting On puncture a few drachmas of clear citron coloured albuminous fluid were removed this was held to indicate that the condition was albuminous periostitis He had not heard of this before, but he finds it mentioned in various French surgical works he has discovered no reference to it in the English works at his disposal Syphilis and tuber

He is told that the prognosis is favourable but in his own case two partial unsuccessful, the swelling though it became smaller persisted He does not suspect any connexion between the intermittent claudication and the albuminous periostitis though both occur in the same limb within a few inches of each other

*. Brief references to intermittent claudication appear in Allbutt and Rolleston's *System of Medicine* and in that of Osler and McCrae In *Taylor's Practice of Medicine* (thirteenth edition, p 382) it is stated that intermittent limping, or claudication may be considered under functional disorders of the vessels, although in most cases there is an underlying structural change The symptoms generally subside after a period of rest but in most cases there is evidence of sclerosis of the arteries or veins or of obliterative arteritis atheroma, or thrombo angitis obliterans The symptoms are said to be due to the affected arteries being unable to carry the increased flow of blood required by the limb during muscular exercise In some cases slight muscular wasting and degeneration of the peripheral nerves (peripheral neuritis) have been observed In many instances the complaint has resulted in dry gangrene of the limb, and in a few cases it has been associated with Raynaud's disease of the upper extremities In cases which do not present any evidence of arterio-sclerosis or obliterative arteritis it is assumed that the condition is due to arterial spasm The attacks may go on for years The treatment recommended is limitation of exercise and avoidance of quelling the circulation up to the point when the vascular obstruction begins to operate Frequent rests in bed may be advisable The local remedies used in Raynaud's disease may be employed and also the constant current electric baths warm baths high frequency currents and gentle massage The condition of the arteries may be ascertained by radiography which will help to determine the extent of the disease Sympathectomy has also been recommended, and the injection of alcohol round the artery

INCOME TAX

"COLONIAL" married and with three children inquires what income tax would be payable in this country on an income of £1,800 per annum derived from investments in South Africa

*. The calculation is as follows

	£	£
	225	1 800
	90	
	—	315
Income taxable		1 485
Of which £225 is chargeable at 2s		£ 22 10 0
And £1 60 is chargeable at 4s		2 2 0
Total tax		£24 10 0

It should perhaps be added that an allowance is also made for South African tax paid, up to a maximum of one half 'Colonial's' appropriate United Kingdom rate

LETTERS, NOTES, ETC

HIGH BAROMETRE AND SUDDEN DEATHS

"A. O. W." writes About forty years ago I began to notice that three elderly women with 'heart trouble' used to send for me to visit them almost on the same day, they had no knowledge of each other I next observed that their messengers used to arrive when the barometer was unusually high Ever since then I have been interested in similar observations On November 19th, a friend told me he had had word that morning of three deaths within his circle, two certainly from 'heart failure' The same day I saw in the *Times* announcements of several sudden deaths 'from heart failure,' definitely so stated, in two cases The attention of the whole world has been riveted on the death of Queen Alexandra from 'sudden heart attacks,' to-day (Monday, November 23rd) the *Times* death column contains notices of five cases of sudden death, three of which are stated to be due to 'heart failure' For the past week the barometer has stood remarkably high over England particularly the south and east I feel convinced that there is more than coincidence here but I cannot advance any satisfactory explanation Obviously one ought to know whether the 'heart trouble' was myocardial or valvular only and if valvular, which valve especially before enunciating any definite view Still it seems worth while to call attention to facts in the hope that some day the explanation forthcoming may assist preventive medicine

RASHES PRODUCED BY VERONAL AND ITS CONGENERS

DR. I. SACKS (Zastron South Africa) reports a dermatosis following the administration of luminal in which the rash differed from those mentioned in the *Lipitone* of October 3rd (paras 271 and 272) A girl, aged 18, who had had epileptiform seizures from birth and was mentally deficient, was treated by luminal in doses of 1 grain twice a day for over two weeks She then suddenly developed a typical scarlatiniform rash which covered the body Her face was brightly flushed and so oedematous that the eyes could not be opened for some days The pulse was fairly quick but there was no rise of temperature One or two attacks of vomiting occurred and the breathing was laboured The urine contained some albumin Under treatment with calcium lactate and magnesium sulphate the rash disappeared in a few days The patient was subsequently treated again with luminal with no ill results but with decidedly beneficial effect on the epileptic attacks and the mental condition

ELDERLY NURSES IN DISTRESS

The trained nurse of to-day, with her easier hours, better pay, and her status assured by State registration is reaping the harvest sown by the early pioneers many of whom struggled through an incomplete training worked for a mere pittance for many years and now find themselves forgotten and in poverty The Nurses' Fund for Nurses has been started to raise enough to allow the older women to spend their declining years with at least enough to eat and a roof over their heads Some of the cases are pitiful—all are elderly or in poor health many have only dimblement benefit of 7s 6d a week or the old age pension of 10s If enough money can be collected it is hoped to buy one or two houses where some of them could have a room at a nominal rent The address of the Fund, which is managed by a committee of nurses is—Care of the *Nursing Times*, St Martin's Street London, W.C.2

MOTOR CYCLE LICENCE HOLDERS

THE Automobile Association informs us that the police have received instructions to enforce the law regarding the position of licence holders on motor cycle combinations Medical motor cyclists should note that by carrying licence holders attached to their number plates they are liable to prosecution

VACANCIES

NOTIFICATIONS of offices vacant in universities medical colleges and of vacant resident and other appointments at hospitals will be found at pages 69 70 71 74 and 75 of our advertisement columns and advertisements as to partnerships assistantships and locumtenencies at pages 72 and 73 A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 196

DIAGNOSIS AND TREATMENT OF SPLENIC ENLARGEMENT IN CHILDREN*

BY

SIR HUMPHRY ROLLESTON, BART, KCB, MD,
FRCP,

PEGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE

INTRODUCTORY

ENLARGEMENT of the spleen is a physical sign, like jaundice, due to many causes, which in the vast majority of cases are infective, though in many instances, such as in von Jaksch's anaemia and aplastic anaemia, it may be impossible to go further than to assume such an origin. The more unstable condition, as regards response to stimulation, of the blood-forming organs in early life as compared with that in adult life makes the significance of the blood picture a difficult and therefore an interesting problem.

The spleen and the lymphadenoid tissues generally are more prone to active response and enlargement in childhood than in later life, and the spleen in particular is more distensible than in adults. In considering the subject it will be well to take conditions in which the spleen is very definitely enlarged, and not to include cases in early infancy in which the edge can be felt just below the ribs, this is of less significance in early infancy than in subsequent years. In G. Carpenter's series of 348 cases of enlarged spleen in children under 12 years of age, 94 occurred in the first six months of life and 220 under 18 months of age, it is probable that some of these were due to rickets deformity displacing the spleen downwards rather than to real splenomegaly.

A special point of interest in connexion with splenic enlargement is in the early stages of the chronic diseases in which it is recognized as occurring, when the other manifestations characteristic of the fully developed disease have not appeared. In some instances splenomegaly may constitute the chief or only clinical sign of an incomplete or fruste form of a disease—for example, in chronic haemolytic jaundice and Hämot's cirrhosis. A palpable spleen has been found as the only physical sign in a family in which other members had Hämot's hypertrophic biliary cirrhosis (Boinet).

A question deserving discussion is the probability that in some cases splenic enlargement is due to more than one factor—for example, syphilis complicated by a low grade streptococcal infection or by tuberculosis. Syphilis may well favour a secondary infection, and then (vide infra) anti-syphilitic treatment may fail to be curative.

It would no doubt be convenient to group the forms of splenomegaly under a number of inclusive headings, such as (1) those that may be familial (chronic splenomegalic haemolytic jaundice, Gaucher's disease, and congenital syphilis), (2) those associated with changes in the blood picture (anaemia, haemolysis, erythraemia, leukaemia), (3) those definitely infective, whether acute, as in enteric fever, or chronic, as in congenital syphilis and tuberculosis, (4) those of tropical origin (malaria, kala-azar), (5) mechanical (growths, cysts, infarcts), (6) associated with hepatic enlargement or cirrhosis. But though this arrangement is attempted, there is obviously such an amount of overlapping as to render it of little value, except as a means of arranging the various conditions in some order or other.

1 FAMILIAL SPLENOMEGALY

Familial splenomegaly may be due to chronic splenomegalic haemolytic jaundice, Gaucher's disease, and congenital syphilis. In addition, it is well to bear in mind the possibility that familial splenomegaly may occur in other and undetermined conditions. De Lange and Schippers recorded a family of seven in which four children had enlarged spleens, one died from haematemesis and two others underwent splenectomy.

In chronic splenomegalic haemolytic jaundice the diagnosis depends on the examination of the blood for fragility

of the red cells, and the treatment, in cases with symptoms demanding it, is splenectomy. After splenectomy the symptoms of chronic haemolytic jaundice disappear, but the red blood cells hardly ever become normal as regards fragility, thus suggesting that the fragility is an inherent peculiarity. So far this fits in with Naegeli's suggestion that the microcytosis of the condition is evidence that these patients belong to a different type of human species. But against this interesting conception are the observations that microcytosis is confined to those members of a family with chronic haemolytic jaundice (Meulengracht), and that after splenectomy microcytosis diminishes (Whitehead).

The cholesterol content of the blood rises after splenectomy, and this might suggest that the fragility and haemolysis depend on the low cholesterol content, but an equally low content is found in some anaemias without fragility (Campbell and Warner), and it has been thought to depend on the relative proportions of cholesterol and lecithin. Thus the medicinal administration of cholesterol in chronic haemolytic jaundice does not rest on such a logical basis as might have appeared at first. Liver exposures were recommended by Parisot and Heully as the result of benefit in two cases of the congenital form, but subsequent experience does not appear to have been confirmatory.

Gaucher's Disease

This condition (*epithelioma primitif*), first described in 1882 as a neoplasm, is now considered to be a special change in the reticulo-endothelial system, and from its racial (Jewish), familial, sexual, and congenital characters has been regarded as a constitutional anomaly, a mutation in the human species (Naegeli, Waugh and McIntosh). It is a striking but rare disease, in 1924 Conner referred to 24 recorded cases. It is familial, but this has not always been established—for instance the sixth recorded case in France was the first shown to be familial (Harrier and Lebeecq). Though the condition involves the spleen, lymphatic glands, liver, and bone marrow probably simultaneously, it is most obvious, both in point of its chronological appearance and objectively, in the spleen, which may be larger than in any other disease suitable for splenectomy, the superficial lymphatic glands are very seldom enlarged. From the distribution of the lesion splenectomy cannot be expected to bring about a real cure, but it gives relief. In Harrier and Lebeecq's 13 collected cases of splenectomy (9 adults, 4 children) there were 3 deaths after operation, and among 51 collected splenectomies in patients under the age of 14 years 4 were for this condition (Bartlett). It is characterized by a peculiar yellowish wedge-shaped thickening of the conjunctivae, commonly seen on both sides of the corner. According to Brill and Mandelbaum, the skin, though showing a peculiar brownish-yellow discoloration in areas exposed to the light, is never jaundiced. Now as the reticulo-endothelial system is concerned with the formation of bilirubin out of haemoglobin, the interesting question arises whether jaundice can occur in Gaucher's disease, observations with Hijmans van den Bergh's test should throw light on this point. It is noteworthy that in Willmoet and Meckenzie Douglas's case of an adenoid tumour with extensive degeneration of the reticulo-endothelial system anaemia and jaundice were absent.

Splenic Enlargement in Congenital Syphilis

This was first pointed out, at any rate in this country by Gee in a paper read before, but not deemed worthy of inclusion in the *Transactions* of the Royal Medical and Chirurgical Society. Gee found it in 25 per cent of his cases, Still in 45 per cent. Mufin in 50 per cent, and Conitts in 63 per cent. It is an index of the severity and activity of the infection in infants born with syphilitic manifestations it is almost always enlarged, in cases in which they appear later the spleen may enlarge before they become obvious, but usually this sequence is reversed, hence the variations in statistics may be explained.

In older children splenic enlargement associated with anaemia should always suggest syphilitic infection and the Wassermann or the therapeutic test. The imitation of

*Being the opening paper of a discussion on this subject in the Section for the Study of Disease in Children of the Royal Society of Medicine on November 27th.

splenic anaemia and the further stage of Banti's disease by delayed congenital syphilis is well known.

In children with an enlarged spleen and a positive Wassermann reaction antisyphilitic treatment may be disappointing, and there may not be any improvement until splenectomy has been performed. Farley has collected seven cases, not including Weil's, but all except French and Turner's were in adults. In such a case, reported by Osman, failure of salvarsan led to splenectomy, when the liver was seen to be cirrhotic, this was followed by apparent cure with a negative Wassermann reaction for six years, when haematemesis and cerebral symptoms proved fatal. The patient of French and Turner, a boy aged 5 years, in whom the blood picture had previously been that of von Jaksch's anaemia pseudo leukaemica infantum, was very similar, except that cirrhosis was not recorded and that a younger sister also had splenomegaly.

The interesting question arises why antisyphilitic treatment fails to exert a curative action, Weil, indeed, suggested that the Wassermann reaction was due to an unknown parasite, but perhaps the more probable view is that syphilitic infection had been complicated by a secondary infection in the spleen, like that presumed to be responsible for the chronic splenic anaemia of adults.

2 CASES ASSOCIATED WITH CHANGES IN THE BLOOD PICTURE

Acute Leukaemia

In early life acute leukaemia is probably more often of the myeloid or myeloblastic than of the lymphoid type, it should be recognized by the blood examination. If acute progress occurs in cases previously latent the spleen may reach a large size. Except in the rare cases, such as Cabot, Michaud, and Arthur Hall's, which turn out to be examples of the lymphocytosis of acute infection,¹ and thus imitate acute lymphoid leukaemia, the prognosis is hopeless, and treatment with benzol, radium, x-rays, and arsenic fails even to retard the inevitable end. Splenectomy, which W. J. Mayo carried out after preliminary x-ray exposures in 31 cases, with beneficial results in more than a third of the patients, does not appear to be suited to the acute cases in early life.

Murray H. Bass has recorded unusual eosinophilia with splenomegaly in a girl aged 6 years belonging to the small group of cases in the adult called eosinophilic leukaemia, the white count (25,600) showed 37 to 64 per cent of eosinophils, with 6 per cent of eosinophil myelocytes.

Pernicious Anaemia

Pernicious anaemia is very rare in early life, but aplastic anaemia occurs, and from examination of a blood film only may suggest acute lymphoid leukaemia or the existence of the rather discredited entity leukaemia.

Thrombocytopenic Purpura Haemorrhagica

This may be (a) primary and constitutional, or (b) secondary to infection, such as by *Streptococcus haemolyticus*, drug poisoning (such as by benzol), and such morbid conditions as nephritis, hepatic cirrhosis, and leukaemia. It may be acute and even fulminating, or chronic and recur for years. It is characterized by a diminution in the number of the blood platelets, from the normal 250,000 to 40,000, 5,000, or lower, a normal coagulation time and a prolonged bleeding time often exceeding two hours (Dukes), and in the active stage by some enlargement of the spleen. There are various views as to the evil influence of the spleen in this condition, and as to the mechanism of the good results of splenectomy introduced by Frank of Breslau in 1915, and followed by Kazanek of Prague (1917), Bull and Rosenthal (1923) in New York, B. Vincent (1925) in Boston, Cowen (1925) in Australia, and Sutherland and Williamson (1925) in London. Ricardo and Albo report cures by splenectomy of chronic haemorrhagic purpura without splenomegaly. Frank suggested that the spleen inhibited the activity of the bone marrow, Kazanek that it removed platelets from the blood, and Bull and Rosenthal that it produced a toxin.

As to the

et al.

acute lymphocytosis is due to

distinguished from acute lymphoid leukaemia and aplastic anaemia by the blood count, from the haemorrhagic forms of diphtheria and the exanthemata by careful examination, from scurvy by the history, the spongy gums, and the reaction to antiscorbutic remedies. The chronic form can be differentiated from haemophilia by the absence of superficial haemorrhages, the normal platelet count, and the normal bleeding time in the hereditary disease.

In the past the chief form of treatment was transfusion, which had sometimes to be repeated. Splenectomy can now be employed as an emergency measure in acute cases when other means have failed to arrest the bleeding, and in the chronic form is regarded as the best remedy by Vincent who found five fatal cases in almost fifty collected cases of the disease treated by splenectomy.

Infantile Splenic Anaemia

Infantile splenic anaemia, meaning thereby von Jaksch's anaemia pseudo leukaemica infantum (1889), also described by Luzet (1891), whose name is bracketed with von Jaksch's by the French, and also called splenomegaly with anaemia and myelæmia, should be definitely separated from the juvenile form of chronic splenic anaemia of adults, and for this reason von Jaksch's more cumbersome title perhaps has an advantage. It appears, like chlorosis, to have become rare in recent years (Thomson). It is confined to the first three years of life, its maximum incidence falling in the middle of this period, and is characterized by great splenic enlargement, secondary anaemia with leucocytosis (30,000), some relative lymphocytic increase, the presence of nucleated reds, a constant myelæmia (up to 6 per cent), and tendency to spontaneous recovery. It is often associated with rickets, but except for Bereterride and Branchi modern writers do not consider that congenital syphilis, which certainly is found in a proportion (less than half) of the cases, is responsible except by diminishing the resistance to the as yet unknown cause. Marquand recorded the disease in twins, and suggested that some congenital factor is responsible, but the tendency to spontaneous recovery is rather against this view. Thursfield, who has paid special attention to this disease during this century, puts the recovery rate at 65 to 70 per cent, and doubts the suggestion that it is specially frequent in Jews. It is familial, the twins figuring in the frontispiece of Hutchinson's *Lectures on Children's Diseases* when seen at the age of 12 years had recovered and their spleens were no longer palpable, but splenic enlargement may persist after the blood picture has become normal. Bereterride and Branchi of Buenos Aires also differ from the general opinion in taking a gloomy prognostic view, and state that in ten years' experience they have not seen a cure, the possibility that the disease they describe is different from the British form in some respects, etiological or environmentally, naturally arises. In the absence of any definite knowledge of its real cause reliance has chiefly been placed on hygienic measures, splenectomy, which would seem rather unnecessary in the light of the recovery rate, has, according to Bartlett, been carried out in five cases.

Chronic Splenic Anaemia

That chronic splenic anaemia of the form seen in adults may occur in older children I have no doubt. There is rightly some scepticism about the existence of such a condition, and it may fairly be said that it is only cases of unknown origin which can be so labelled. But there are such cases which cannot in the presence of a negative Wassermann reaction, be regarded as syphilitic, unless the view be taken that the splenomegaly is the legacy of a spirochaetral infection which has died out. Some young adults with chronic splenic anaemia have had an enlarged spleen from childhood, I have recorded such a case, and Leech reported a case fatal after splenectomy (spleen 425 grams, or 13 oz.) in a boy aged 9 years with a negative Wassermann reaction. It has been suggested that von Jaksch's anaemia is the infantile form of the chronic splenic anaemia of adults, and that the blood picture depends on the more active response of the blood-forming organs, but the difference in the prognosis—von Jaksch's anaemia often undergoing spontaneous cure, while chronic

splenic anaemia of adults does not—makes this an improbable assumption. I have not any reference to splenic anaemia due to thrombosis of the splenic vein in a child.

Banti's Disease

In Banti's disease and portal cirrhosis with splenomegaly removal of the spleen has sometimes been beneficial (Osman), but the general opinion is that splenectomy is most successful in cases before the liver has become cirrhotic—namely, in the stage corresponding to splenic anaemia and before Banti's disease has supervened. Among 69 collected cases of splenectomy for chronic splenic anaemia—mainly in adults—is shown by the average age of 33 years, the extremes being 2½ and 69 years. Clancy found that 23·3 per cent of the 30 cases showing hepatic cirrhosis proved fatal within forty days of the operation, whereas in cases without hepatic cirrhosis the corresponding mortality was 13 per cent. Richards and Day found that in Egyptian splenomegaly, in which hepatic cirrhosis is an early accompaniment, splenectomy was beneficial if performed before the appearance of ascites.

Erythraemia

The spleen is nearly always enlarged in this condition, which, however, is rare in childhood. In his monograph on the subject Parkes Weber refers to about six cases in early life, two of which were probably associated with congenital syphilis. Poynton, Thursfield, and Paterson recorded a case in a girl aged 3½ years. Splenectomy is inadvisable as the spleen serves as an overflow for the excess of blood. Benzol by the mouth and x-ray exposures of the long bones may be tried, and the question of intestinal infection and toxæmia should be considered.

3 CASES OF INFECTIVE ORIGIN

Infective Splenomegaly

Infective splenomegaly as part of an acute general affection of the haemopoietic system is very rare. I have seen a mixed infection of the glands, which in places were breaking down, due to *B. coli* and streptococci. Osman reported a case of anaemia with splenomegaly associated with tonsillitis in a boy aged 6½ years who was in good health eight years later. Infarcts and enlargement of the spleen in malignant endocarditis, and the spleen of enteric fever, should be recognized by the special features of the causal disease.

As regards chronic infections, the field is large. Perhaps the palpable spleen sometimes present in status lymphaticus may, like that condition, be due to a low grade infection, as suggested by H. C. Cameron. In Still's disease, or the juvenile form of rheumatoid (chronic infective) arthritis, the spleen and lymphatic glands are enlarged, and amyloid change has been reported.

Tuberculosis of the Spleen

Tuberculosis may give rise to very considerable enlargement, both in acute miliary tuberculosis and in the chronic form. In chronic tuberculosis the organ may contain comparatively large caseous masses, resembling to the naked eye lymphadenoma. There may be adhesion to the diaphragm so that the organ, though increased in size, cannot be felt. Owing to the perisplenitis there may be pain and tenderness, and Thursfield considers that tuberculosis is the only condition of the organ in which it is often distinctly tender.

Lymphadenoma

This is not uncommon in older children, but it is very rare to find it predominantly splenic as in a boy aged 11 years, recorded by Poynton, Thursfield, and Paterson, in this case the spleen weighed 25 oz, the liver 44 oz, both being invaded with the growth, the cervical glands are practically unaffected. Among five cases of lymphadenoma recorded by these writers two had jaundice.

Hyperplastic Lymphatic Splenomegaly

The relative value of splenectomy and x-ray exposures in disease accompanied by splenomegaly is obviously a matter of practical importance. In spite of the tendency to produce adhesions, and so render subsequent operation

more difficult, x-ray treatment would appear to be worth a trial in cases of splenomegaly of doubtful origin, as they may be examples of the condition called by Bull, Bachr, and Rosenthal "splenomegalia lymphatica hyperplastica." They record three cases, none in children, in two, one of which proved fatal, splenectomy was performed, and then it was found that radiotherapy caused complete disappearance of the general lymphatic gland enlargement and reduction of the spleen to its normal size. The condition, which may sometimes pass unrecognized, is characterized by a normal blood count, general enlargement of the lymphatic glands, and great splenomegaly. The microscopic appearances are enormous enlargement of the Malpighian bodies, which are almost entirely composed of endothelial or reticular cells, and of the follicles of the lymphatic glands which show a similar structure. The condition is not influenced by aise, but is rapidly cured by exposures to the x rays.

4 TROPICAL SPLENOMEGALY

Kala-azar

The infantile form of kala-azar may be seen in children who have come from countries where it is endemic, and the diagnosis depends on the detection of the Leishman-Donovan parasite by splenic puncture. The liver and the spleen are enlarged, but as compared with other conditions are soft to the palpating hand. It occurs in the Mediterranean littoral, Malta, Egypt, and elsewhere, and probably many cases of typical splenomegaly are due to kala-azar. The ponos* of the Greek islands Spetsi and Hydra is of this nature. This febrile splenomegaly has been reported in children in the South of France (D'Oelsnitz, Daumas, Liotard, and Puech), and Wyllie has recorded one in a child who came from Malta to England. The treatment is the intravenous injection of tartar emetic and sodium antimonyl tartrate solutions (Rogers). After failing with medical treatment Talbot and Lyon obtained a cure from splenectomy in the first reported cases of infantile kala-azar in America.

5 MECHANICAL CAUSES

Enlargement of the spleen due to primary new growth, hydatid and simple cysts, angiomas, and abscess are very rare. Among 57 collected cases of abscess in children 14 only were recognized clinically (La Ferla).

Reference has already been made to the cases with hepatic enlargement or cirrhosis.

THE STRENGTH OF INSULIN PREPARATIONS

A COMPARISON BETWEEN LABORATORY AND CLINICAL MEASUREMENTS

BY

WITH AN INTRODUCTORY NOTE BY

H H DALE, M D, F R S

I—INTRODUCTORY

The decision of the discoverers of insulin and their colleagues in Toronto to indicate the strength of the preparation in "units" of activity was undoubtedly sound, and has led to a highly satisfactory precision in its dosage. So far as this country is concerned, experience may be divided roughly into three periods.

In the first no final definition of the unit had been given, and only rough methods were available for its measurement in the laboratory. On the other hand, physicians had yet to learn what regularity of effect could be obtained with a really constant preparation, so that comparatively few complaints were heard of the differences in strength between similarly labelled batches of the solution, though it can hardly be doubted that such occurred.

In the second period, though the unit had received its final physiological definition, and a representative batch of solution had been received in this country to serve as a standard of comparison, a trustworthy method for its measurement on normal animals was still being sought. Physicians, on the other hand, with time and opportunity, had found that a patient whose diet and activities were under complete control was a very constant reagent for insulin. The effect of each daily dose on such a patient, if followed with sufficient care, provided a reasonably accurate measure of the activity of the preparation. Clinical observation, for the time being, had attained a greater accuracy than laboratory methods of assay, and it was to be expected that discrepancies would be observed, such as those collected below by Drs Harrison and Lawrence in Table III. The suggestion naturally arose that a clinical assay of each batch of insulin should supplement that made in the laboratory before the final adjustment of its strength for issue. The Insulin Committee of the Medical Research Council decided first to organize a careful and deliberate comparison between the results of laboratory and clinical assays, on a selected series of samples.

By the time this decision was taken, however, the third period had been reached. There was reason now for hope that the laboratory test had again overtaken clinical observation in accuracy. The method devised and described

below by Mr Marks had aimed at eliminating the effect of the wide individual differences of response shown by different animals, as thoroughly as such differences were eliminated in the clinical tests on patients of known reaction. It had endeavoured to go further, and to neutralize even the day-to-day variations of sensitiveness to insulin shown by the same animals. The comparative trials now undertaken had, moreover, the advantage that clinical and laboratory measurements were to be made at the same time, whereas many of the discrepancies earlier apparent had resulted from clinical trials made many months after the laboratory assay, at a time when the preparations of insulin were less stable than the highly purified products now available. The results of this organized comparison, as shown in Table IV of the report of Drs Harrison and Lawrence, fully realized the expectation that the laboratory method of assay, now for some time in use at the National Institute, would be able to hold its own with the most careful clinical measurements. The correspondence is so good, indeed, as to justify the conclusion that the assay on rabbits here described by Mr Marks, if conscientiously carried out, can fix the activity of a preparation with an accuracy that no clinical test is likely to improve.

It should be added that experience in this department with preparations standardized by other methods suggests that these also are capable of an accuracy well within the range of clinical needs, when carefully carried out in comparison with the stable standard now adopted for international use.

H H D

II—THE BIOLOGICAL ASSAY OF INSULIN PREPARATIONS IN COMPARISON WITH A STABLE STANDARD

BY

H P MARKS

The original physiological unit of insulin was defined as the smallest dose which would lower the blood sugar of a 2 kilogram rabbit, starved for twenty-four hours previously, to the convulsant level of 0.045 per cent, and this unit, with the clinical unit later based on it (1 rabbit unit = 3 clinical units), has been generally accepted. The word "unit" is here used throughout to mean such a "clinical" unit, the original or "physiological" unit being now only of historical interest.

All the earlier methods of assay based on this definition, whether they involved the observation of actual convulsions or of the fall in blood sugar produced by a subconvulsive dose, aimed at determining the potency of a sample of insulin absolutely in terms of an animal reaction.

THE STANDARD OF REFERENCE

As it became evident that such a reaction could not furnish an invariable standard, an attempt was made in this laboratory to standardize rabbits by determining their response to a given dose of a stable reference sample whose potency had been verified at Toronto. The response of these rabbits to the sample under test was then compared with their response to the standard sample, so that, in effect, the potency of the unknown sample was expressed in terms of that of the standard preparation. Such was the state of affairs at the time when the laboratory tests were performed on the batches in Table III of the clinical report. Effort was directed to improvement of the laboratory test, so as to take full advantage of direct comparison with a standard sample of constant potency. Meanwhile we had replaced the original reference sample of insulin solution by a purified, dry preparation which could be relied upon to retain its potency unchanged. A similar preparation, made at the request of the International Conference on Biological Standards, has now been accepted for international use, and the unit of insulin has been defined by the Insulin Committee of Toronto in terms of that standard preparation.

THE METHOD OF COMPARISON

In the experience of this laboratory, as also in that of Macleod and Orr, it has been found repeatedly that, for either of two reasons, convulsions may fail to occur in a

rabbit injected with a dose which produces them in others. The rabbit may be abnormally insensitive to the action of insulin on the blood sugar, so that this only falls to a small extent, or, on the other hand, the rabbit may be quite normally sensitive, according to the indication of the effect on its blood sugar, but show practically no symptoms.

We might distinguish these two types of insensitiveness to the convulsant action of insulin as "metabolic insensitiveness" and "neurotic insensitiveness." The latter condition, in which the rabbit may exhibit no overt abnormality, though its blood sugar fall as low as 0.05 per cent, can apparently be developed to some extent by habituation. It is certainly much commoner in rabbits which have been used for many tests with these larger doses than in those which have been so treated a few times only.

In view of these facts, it is obvious that no reasonably accurate estimate of the activity of a sample can be made from the proportion of convulsions observed on a small number of rabbits, and, indeed, we are informed that those who have used this method with success have found it necessary to use relatively enormous numbers in order to obtain consistent results. Attention has therefore been directed to determining as accurately as possible the hypoglycaemic response to a subconvulsive dose, as involving fewer factors of possible variation than those which must complicate the tests based on observation of convulsions or death. Thus direct determination of hypoglycaemic effect is the basis of Macleod and Orr's method, as now used by the Insulin Committee of Toronto. But, in that form of the test, individual differences and periodic fluctuations of metabolic sensitiveness remain, and have to be eliminated as far as possible by many repetitions. Our aim has been to make the test based on blood sugar determinations strictly comparative, and to eliminate individual variations altogether, by using the same animals for the test on the unknown sample and on the standard.

The matter would be simple if the animals, though differing widely among themselves, exhibited an individual constancy of reaction. It would only be necessary to standardize each rabbit by determining its reaction to a given dose of the standard, with which the reaction to a dose of the sample could then be compared. For some time we experimented with this method of comparison, but control experiments, in which the same group of rabbits received the same dose of the same preparation once a week, brought to light the fact that each rabbit showed, in varying degree, fluctuations of response on either side of its characteristic average. It might be supposed that, if a sufficient number of animals were used, these fluctuations would tend to cancel one another, but we found pronounced tendency to a simultaneous rise or fall from the characteristic averages affecting all the rabbits together.

No increase in the number of animals used could eliminate a variation affecting the whole stock. On the other hand, if the variations were really simultaneous and equal, we could eliminate their effect entirely by dividing the rabbits used for the test into two equal groups—one receiving the sample under test and the other the standard preparation—and then repeating the test a few days later with reversal of the groups. This method has been used here for some time, and was employed in that later part of the present comparison which was officially organized.

It is not suggested that the periodic fluctuations really show the strict parallelism required to make the method perfect. Different animals would appear to vary in their tendency to these fluctuations. All that is claimed is that the method, by ensuring that each rabbit receives both the sample under test and the standard, and that the effect of day-to-day variations is spread as evenly as possible over the whole series, eliminates the effect of permanent individual differences altogether, and that of periodic variations as far as is practicable.

DETAILS OF METHOD

The details of the method employed were as follows:

1. Choice and Care of Stock

There is no restriction on the breed of rabbits used, but greater uniformity in response is aimed at by eliminating from the stock all rabbits in which a dose of 1 unit per kilogram produces convulsions (usually about 15 per cent of the rabbits), and all those

which prove to be abnormally insensitive. Their weight should be between 2 and 3 kilograms.

The temperature of the animal room and of the room in which the tests are carried out, is maintained as nearly as possible at 65° F. throughout the year. The diet consists mainly of oats (about 100 grams a day for a rabbit of 2 kilos) with cabbage leaves and fresh grass when obtainable. A diet containing sweet turnips was discontinued owing to the rapid decrease in sensitiveness which followed.

Twenty-four hours before a test all food and litter is removed from the cages of the rabbits to be used, but water is left till just before the commencement of the test. Rabbits should not be used more than twice a week and the stock should be large enough to enable each rabbit to have a frequent rest.

2. General Procedure

A batch of not less than six rabbits having been prepared for test by withholding food as above, samples of blood for the estimation of blood sugar are obtained by puncture from the lateral ear vein, a vigorous circulation being promoted by warming the ear over a carbon filament lamp and by friction if necessary. Slightly more than 1 ccm of blood is collected in a small glass vessel containing a trace of powdered potassium oxalate and the estimation of blood sugar carried out according to the method of Shaffer and Hartmann (1920). This method lends itself well to a large number of estimations, but any other suitable method may be used.

A sample of blood for the estimation of the normal fasting blood sugar is taken immediately before the injection and further samples at every hour subsequently over a period of five hours. It is felt that by this means a more accurate picture of the hypoglycaemia following the injection is obtained than by determining the blood sugar level at only three intervals after injection as in Macleod and Orr's method. The period of five hours as used by Macleod and Orr for the duration of the experiment, is adhered to as in our experience the blood sugar usually returns to about the normal level at the end of five hours.

The injection is given subcutaneously. To obtain a suitable volume for injection, commercial samples of the usual strength—namely 20 units per cubic centimetre—should be diluted ten times with distilled water and the appropriate volume injected with a syringe graduated to 0.01 ccm (tuberculin syringe).

Half the rabbits are injected with a dose of the standard preparation (diluted as above said) adjusted to the weight of the rabbit, and representing 1 unit per 2 kilograms while the other half are given a theoretically corresponding dose of the sample under test (see 3 below). After an interval of at least three days the test is repeated on the same batch of rabbits with the difference that the rabbits which previously received the standard are now injected with the unknown sample and vice versa.

3. Choice of Dose

Consideration must be given to the fact that the effect on blood sugar does not increase in direct proportion to the dose but reaches a limit as the convulsant dose is approached. Equal hypoglycaemic effect does not necessarily imply equality of dosage when the doses employed fall near the region of the convulsant dose. It is desirable therefore to choose a dose as far below the convulsant limit as is consistent with obtaining a reaction of sufficient magnitude to be reasonably free from experimental error. A dose of 1 unit (one third of the generally convulsant dose) per 2 kilogram rabbit is found to fulfil these requirements especially when abnormally sensitive and insensitive rabbits from the stock are eliminated as recommended above. Where the general level of sensitiveness of the rabbits is high a smaller dose should be employed—for example 0.8 unit per 2 kilograms.

It has been our custom to adjust the dose to the weight of the rabbit, but there seems to be no reason why body weight should not be regarded as an individual characteristic for the short period occupied by the test and the simpler plan adopted of giving all the rabbits the same amount of injection regardless of their weight. In this case, however, it would seem desirable to set narrower limits on the weights of the animals used.

Although by reference to Table B it may be possible to compare unequal doses with a fair degree of accuracy the most reliable results are obtained when the dosage of the unknown preparation is adjusted so as to be reasonably near the dose of standard used—namely 1 unit per 2 kilogram rabbit.

4. Calculation of Hypoglycaemic Effect

If the test is used in this way as it is primarily intended to be used—namely to compare the effects of two approximately equal doses—the exact relation between hypoglycaemic effect and dose is of little moment and so long as we can arrive at a figure truly representing the hypoglycaemic effect it is unnecessary to bring it into relation with any absolute unit of reaction such as the convulsant dose. For this reason we were led to abandon the Macleod and Orr formula and to adopt the more convenient percentage blood sugar reduction.

This figure—namely the average reduction in the blood sugar over a period of five hours following the injection expressed as a percentage of the initial blood sugar—is arrived at by subtracting the mean of the five hourly blood sugar estimates following the injection from the initial estimate and expressing this difference as a percentage of the initial blood sugar. The following example will make this clear. Initial blood sugar 105 mg per 100 ccm. Blood sugar at 1 2 3 4 and 5 hours after the injection = 65, 61, 83, 88 and 99 mg per 100 ccm respectively. The mean of the figures for the five hours following the injection is 80 so that the figure for the hypoglycaemic effect is

$$\frac{105 - 80}{105} \times 100 = 24.5 \text{ per cent}$$

STRENGTH OF INSULIN PREPARATIONS

Having calculated the percentage blood sugar reduction in this way for each injection we now find the sum of all the figures relating to the injections of the sample, and of all those relating to injections of the standard. A comparison of these two totals will then indicate whether the particular dose of the standard under test is more or less active than that of the standard preparation and approximately the extent of the difference.

TRIAL OF THE METHOD

The essential requirements for the validity of the method, applied in this manner, are that equally active doses should give equality of effect and that differences in dosage should be made manifest by roughly proportional differences in effect. To what extent these requirements are satisfied may be gathered from a consideration of the following results of experiments, in which (1) the standard preparation was simply substituted for the unknown sample, so that, in effect, the activity of the standard preparation was compared against itself, and (2) the effects of various proportional doses of the standard were compared with that of the standard dose of 1 unit per 2 kilograms.

1. Comparison of Equal Doses of the Standard Preparation

The results of a typical experiment are set out in the following table

TABLE A

Rabbits receiving Standard Preparation (1 unit per 2 kilos)	Percentage Blood Sugar Reduction	Rabbits receiving Sample (in this Case Standard Preparation—1 unit per 2 kilos)	Percentage Blood Sugar Reduction
First day—			
No 7	52.2	No 43	37.0
No 8	49.3	No 44	40.6
No 9	35.8	No 45	41.7
	117.3		119.3
Second day—			
No 43	49.6	No 7	39.1
No 44	44.5	No 8	53.1
No 45	41.8	No 9	48.6
	136.0		140.8
Total for both days	253.3		260.1

It will be seen that although the rabbits as a whole gave a greater response on the second day than on the first, the totals for the whole test differed by only 2.7 per cent. Theoretically they should be identical. This is the type of variation which the cross over test particularly aims at eliminating. In addition to this however, erratic responses in single rabbits are occasionally encountered. In order to minimize the effect of these it seems desirable to employ more than six rabbits for a test. The percentage differences between totals in ten such tests were 1.4, 0.2, 2.7, 13.4, 15.8, 3.9, 1.9, 5.0, 2.5, 1.2 and indicate the degree of accuracy to be expected. The standard error for the series is 7.0. Two of the above differences are unusually great and if full data had been available concerning the normal response of the rabbits concerned, might have been eliminated. They have been included to show the method at its worst as well as at its best. If these are eliminated the standard error is only 2.5.

2. Comparison of Unequal Doses of the Standard Preparation

As already pointed out it is not sufficient merely that equal doses should produce equal effects; a significant difference in dosage must further give rise to an unmistakable difference in effect. In order to determine what difference in effect was produced by a difference of 10 per cent in the dose further tests were carried out on the lines of those already described with the difference that a dose of nine tenths of a unit was compared with the standard dose of 1 unit per 2 kilogram rabbit. The results were 92.5, 93.6, 91.4, 96.0, 89.0, 97.9, 97.2, 98.5, 91.5. The mean of all the tests gives a figure of 94 per cent effect of 1 unit, while the variation from the mean is 3.1. Similar series of tests were carried out on other proportional doses. The results of all the tests are summarized in the following table from which the potency of a sample giving a total hypoglycaemic effect different from that given by the standard may be roughly estimated.

TABLE B—Effect of Unequal Doses

No of Tests	Dose, as Percentage of Standard Dose	Effect as Percentage of Effect of Standard Dose	Standard Error
7	110	106	3.7
10	100	100	7.0 (2.5)
10	90	94	3.1
7	80	83	6.3
7	75	78	10.7

A Simplified Procedure

The desirability of using more than six rabbits for a test has already been indicated. With a view to enabling this to be done, by reducing to a minimum the labour involved in taking samples of blood and estimating the blood sugars, trials have recently been made in which the mean value of the blood sugars for the five hours following the injection has been determined directly on a pooled sample. It is then only necessary to collect 0.2 c.c. of blood at each hour, the five-hourly samples for a particular rabbit being delivered into the same tube containing 8 c.c. of N/12 sulphuric acid. It is better, however, to take all samples in duplicate, so that 0.4 c.c. of blood is taken at each bleeding. At the end of the experiment the whole is defecated by the addition of 1 c.c. of 10 per cent sodium tungstate. This simplified procedure is found to give results agreeing closely with those based on separate 1 c.c. samples, taken at the same times, estimated separately, and arithmetically averaged.

Using this method, it is quite practicable to conduct a test on ten or twenty rabbits, and so minimize the error introduced by occasional erratic responses.

III—CLINICAL ASSAYS OF INSULIN PREPARATIONS

BY G. A. HARRISON AND R. D. LAWRENCE
Commercially manufactured insulin became generally available in Great Britain in 1923. In those early days it was obvious clinically that batches from different sources varied widely in strength (Table I). It was necessary, however, in order to save the lives and relieve the sufferings of diabetics, to place insulin on the market as quickly as possible.

TABLE I—Comparison between Two Batches of Insulin under Identical Conditions and in a Single Day (G. A. H.)

Period after Insulin	Blood Sugar Mg per 100 c.c.	
	Batch A (10 Units)	Batch B (40 Units)
Immediately before		220
One and a half hours	05	223
Two and a half hours	164	174
Four hours	113	110

It will be seen that 20 units of Batch B was not so efficacious as 10 units of Batch A. This comparison was made in early days (1923) before the methods of standardization were satisfactorily established. Batch A was made by a different firm from Batch B. Such gross differences are probably never to be met with nowadays. Certainly two batches made by the same firm would never exhibit such wide differences now.

Complaints from clinical workers as to variations in the potency of different batches were very few and then some times contradictory. This no doubt, was mainly due to two reasons. First, very few physicians maintained the blood sugars of their patients for long periods close to the level at which hypoglycaemic symptoms occur, and most therefore failed to observe variations in the strength of different batches. Secondly, all physicians were intent on learning how to use the drug to the best effect, and were trying different doses and methods of treatment, and therefore

TABLE II—Clinical Comparison of Different Batches of Insulin which had been passed as of Uniform Strength as a Result of Rabbit Tests (R D L)

Note—Breakfast half an hour and lunch four and a half hours after insulin. Second dose of insulin given eleven hours after first. Glycaemia 85 mg per 100 c cm blood.

* Hypoglycaemic symptoms. 5 grams of sugar given April 16th but no sugar on April 18th.

described observed changes to factors other than insulin. It was only later that constant methods and refinements in handling patients led to the detection of small variations in the strength of different batches.

Early in 1924 a few workers, whose plan was to keep the blood sugars of their patients fairly normal (between 180 and 80 mg per cent), and who were employing large doses of insulin to do so in severe cases, reported that the variation in the potency of insulin was sometimes very noticeable. A typical experiment by one of us (R D L) is given in Table II, and the conclusions in Table III are based on such experiments. It was further noted that the results of assay on rabbits and of clinical tests on human patients occasionally showed marked discrepancies.

Early in 1925 we began the clinical assay of the specially selected series of samples, under the conditions mentioned above by Dr Dale. We always worked independently of each other, and on different patients. At the end of the inquiry the results from the three sources—the National Institute, the Hospital for Sick Children, and King's College Hospital—were compared. A summary is given in Table IV. It will be seen that, considering the many incompletely controllable factors (such as a variable glycogen store, etc.) inherent in such experiments, the three sets of results are exceedingly close to one another.

TABLE III—Comparison between Rabbit Tests and Clinical Tests in 1924

Results Expressed as Percentages of a Common Standard

Batch No	Rabbit Tests (H P M)	Clinical Tests (R D L)	Batch No	Rabbit Tests (H P M)	Clinical Tests (R D L)
D	67	100	I	100	100

It will be noted that Batch I is 100 per cent in Table III and 80 per cent in Table IV. In the summer of 1924 it was 100 per cent according to both rabbit and clinical tests. Six months later it was 80 per cent according to clinical tests. As a result of repeated clinical tests its potency appeared constant at 80 per cent for the next five months. At the end of eleven months the total rabbit tests resulted in a figure of 80 per cent of the standard. It would appear,

TABLE IV—Comparisons between Rabbit Tests (Marks's Method) and Clinical Tests in 1925

Results Expressed as Percentages of a Common Standard

therefore, that some solutions of insulin may deteriorate with long keeping.

We have been led by this comparative experiment to the following conclusions:

1. Rabbit tests by Mr Marks's method are quite satisfactory for the control of the potency of different batches of insulin for clinical use.

2. Clinical tests, if carefully carried out, are quite as delicate as the best of rabbit tests. Owing to the practical difficulties of clinical testing it is fortunate that they are not essential for the final adjustment of the strength of batches of insulin for clinical use.

3. There would appear to be no evidence of any fundamental difference in the results of tests performed on normal rabbits and on diabetic patients.

4. To exclude variations in potency which might be inconvenient in the clinical use of insulin, it would appear sufficient to recommend that only variations exceeding 10 per cent from the standard need be corrected before issue. The method of assay described by Mr Marks appears to be adequate to secure this.

5. Some solutions of insulin may deteriorate when kept for several months.

METHOD OF PERFORMING CLINICAL TESTS

The five selected patients had been on a fixed daily intake of carbohydrate, protein, fat, and calories for many weeks or months before the period of the tests. The insulin (two doses daily) had been carefully adjusted so that there was no glycosuria (or at most occasional traces) at any time. The blood sugars usually varied between 60 and 200 mg in each twenty-four hours. In the intervals between tests the patients were continuously on the same batch of insulin (Batch I at first, and Batch Q later in the period under review). They were all out-patients and arranged and weighed their own diet.

On the day before each test and on each of the test days the diet was identical, not only in its total food values, but also as regards the articles of food taken. Likewise every detail of the patients' daily routine (the amount of exercise, etc.) was made as exactly alike as possible on each of these days. Charts 1 and 2 show how almost identical curves can be obtained on different days under standard conditions with the same dose of the same batch of insulin.

CHART 1—Blood sugar curves with an interval of six days after the same dose of the same batch of insulin, and on the same diet

Under these conditions it is fair to conclude that differences in the blood sugar curves are due to variations in insulin alone.

On the first test day the usual dose of the standard batch (I or Q) was administered half an hour before breakfast. The sugar content of the blood was estimated before and at hourly intervals after the insulin for five or six hours. The blood sugar results were then plotted. On the second

CHART 2—Blood sugar curves with an interval of ten days after the same dose of the same batch of insulin, and on the same diet

day what was judged to be the equivalent dose of the second batch of insulin (usually the same dose, unless we had obtained previous evidence to the contrary) was injected instead of the standard batch. The second curve so obtained was plotted beside the first. When the curves practically coincided, the doses of the two batches were regarded as equivalent. If the curves did not coincide the test was repeated, making a suitable alteration in the dose of the second batch of insulin. Sometimes the standard was given on the second and the unknown on the first test day. The tests were confined to the five selected patients, who had

much experience in tests of this kind, involving accurate quantitative dieting. Three of the cases were severe and

CHART 3—Comparison of Batch Q and Batch I (first test). B=Breakfast (half an hour after insulin) of carbohydrate 15 grams, protein 15 grams, fat 45 grams. L=Lunch (three and a half hours after insulin) of carbohydrate 15 grams, protein 20 grams, fat 35 grams. Batch Q is obviously stronger than Batch I. It was estimated from the curves in Chart 1 that about 16 units of Batch Q would be the equivalent of 20 units of Batch I. The test was therefore repeated a week later (See Chart 4).

CHART 4—Comparison of Batch Q and Batch I (second test). B=Breakfast (half an hour after insulin) of carbohydrate 15 grams, protein 20 grams, fat 45 grams. L=Lunch (three and a half hours after insulin) of carbohydrate 15 grams, protein 20 grams, fat 35 grams. Sixteen units of Batch Q are equivalent to 20 units of Batch I or, taking Batch Q as 100 per cent, Batch I is 80 per cent.

two moderately severe, thus differing in their power to produce endogenous insulin. But in spite of this the results

obtained in these five individuals were remarkably constant, and in some fifty tests rarely differed more than 10 per cent from the average results given in Table IV. The results are expressed as percentages of the standard Batch Q. Charts 3 and 4 illustrate the manner in which the tests were performed.

It was soon found that certain conditions, apart from the standard conditions mentioned above, had to be observed if the tests were to be trustworthy. Hypoglycaemic symptoms had to be avoided to obtain comparable curves. When an excess of insulin was given, the second half of the curve tended to be flattened out at a level of about 70 to 90 mg per cent, the blood sugar falling but slightly although the action of insulin was still potent (Chart 5). The next dose—that is, the evening dose—of insulin also appeared unusually efficient. Presumably the failure of the curve to continue its fall was due to the extra call to mobilize glycogen as a response to hypoglycaemia, and the unusually good response to the next dose of insulin was due to the fact that there was less glycogen upon which to draw. The best comparisons were obtained when the fasting levels on the two days were approximately the same. Comparisons between standards and unknowns were invariably made on consecutive days. It was of little value to make comparisons when marked hyperglycaemia and glycosuria were present. This would be expected owing to the difficulty of ensuring that the same quantity of dextrose “escaped” the action of insulin in tests lasting for relatively short periods.

All determinations of blood sugar were made in duplicate

and the mean taken. Maclean's method of estimation was used throughout. The dose of insulin was measured in a 1 c.c. syringe graduated in hundredths. Subcutaneous injections were given by the same person in one limb one day and in the corresponding site in the opposite limb on the next day.

An attempt was made to work out an arithmetical method

of comparing different batches. The one which gave the most uniform results was a comparison of the totals of the blood sugar figures obtained on the different test days. For example, if with the same dose of different batches the totals were 500 and 750 mg, the second batch was taken as 50 per cent weaker than the first, the standard batch. This gave results closely similar to the plotted curves. When the initial fasting level were different by 10 or 20 mg, an adjustment was made by subtracting 10 or 20 mg from all the figures, and in most cases this gave very satisfactory results. Thus, if one fasting level was 10 mg higher than the other, and six blood sugar estimations were made, before making the arithmetical comparison 60 mg were subtracted from the higher fasting level total. Sometimes these corrections

gave results which were manifestly inaccurate, especially when the fasting levels were 30 or more milligrams apart. Other arithmetical calculations based on the fall of the blood sugar—either total or over various parts of the curves—were still more inaccurate, and the comparison of the general appearance and range of the plotted curves was found to be far the most consistent mode of comparison.

CHART 5.—Effect of hypoglycaemia on the shape of the curve. Curve (a). Insulin was not given in doses sufficient to produce hypoglycaemia. It will be noted that the blood sugar was falling rapidly between the tests at two and a half and at four and a half hours. Curve (b). A larger dose of insulin was given, hypoglycaemic symptoms started at the end of three and a half hours and continued until lunch (four hours forty minutes). It will be noted that Curve (b) is flattened out between two and a half and four and a half hours whereas Curve (a) is falling steeply at this period. B=Breakfast L=Lunch.

RIGHT-AND LEFT-HANDEDNESS IN PRIMITIVE MEN*

BY

PROFESSOR G. ELLIOT SMITH, M.D., F.R.S.,
UNIVERSITY COLLEGE LONDON

THE statement that the fossilized skull recently found in London was that of a left-handed woman has given rise to widespread incredulity, which in some cases has found expression even in derision. This has not been entirely allayed by the statement published in the *BRITISH MEDICAL JOURNAL* of November 7th, in which I called attention to the very definite evidence provided by the fossilized skull of the reversal of the normal asymmetry of the brain case, and the reasons for associating this reversal with the condition of left-handedness. In that communication (as well as in the *BRITISH MEDICAL JOURNAL* of August 29th, 1908, p. 596) I called attention to the fact that in the winter of 1907-8 Professor Wood Jones and I investigated the significance of this reversal of the asymmetry of the brain case, accepting as the criterion of right- or left-handedness respectively the observation whether the right or the left humerus was the longer and stronger. In the *cranium* I found that the asymmetrical impressions upon the occipital bone were reversed in those cases where the left humerus was longer and more robust than the right.

The question has been raised by several critics as to the validity of these inferences from the size of the humeri as indications of right- or left-handedness. Since 1845, when Arnold raised this problem for consideration, an extensive literature has accumulated from the repeated discussions of the asymmetry of the human body and the difference in the length of the right and left arms. An admirable summary of these discussions is given by the late Professor Grupp in two small books published at Jena in 1909†. On page 7 of the former he summarizes the researches of Arnold, Rollet, Matiegka, Hasse, Dehner, and Guldberg on the question of the excess in length of the left or right arm, and shows that these differences are usually associated with left- and right-handedness respectively. However, he calls attention to the fact that at the time of birth the length of the bones in the two arms is identical. In other words the asymmetry manifests itself in the course of post-embryonic life. Grupp further points out that occasionally it happens (in people whose occupation compels them to exercise the left arm more than the right) that a person with a congenital tendency to right-handedness may have longer and stronger bones in the left arm. This state of affairs, however, is altogether exceptional, and should not be allowed to discredit the clear inference from a large mass of evidence that the length of the arm bone in the great majority of cases is a safe indication of right- or left-handedness.

FIG. 3.—Similar view of the endocranial cast of *Pithecanthropus* with large lunatic sulcus (L) on the right hemisphere and a small and smaller sulcus (S) on the left

[Drawings by A. K. Maxwell]

During the course of his work in Nubia in 1907 Professor Wood Jones attempted to correlate his observations on the skeletons of the ancient inhabitants of Nubia with the conditions found in living Egyptians, and he discovered that in right-handed living people the left clavicle was longer and thinner than the right. Then, proceeding to examine the bones in the skeletons, he found in those cases where the right humerus was longer and stronger than the left that the left clavicle was longer and thinner than the right. Moreover, he found that when the clavicular condition was reversed (and the right one was longer and slenderer than the left) the left humerus was then the bigger bone. He regarded this as a confirmation of the use we had made of the humerus as an indication of right- or left-handedness.*

Looking through any extensive collection of measurements of human skeletons, it will be found that the means of the lengths of the right humerus are definitely greater than those of the left.

The asymmetry of the brain (Fig. 1) that is associated with this asymmetry of the limbs is not restricted to modern man. It is characteristic of the human family as a whole, and it seems to be one of the distinctively human traits revealed in most of the known fossil material. For instance, in the cast of the brain case of the La Chapelle man, which has been described by Professors Boule and Anthony, a large lunatic sulcus is shown upon the left hemisphere, and in this skeleton the right humerus is longer than the left. In the Neanderthal group as a whole, however, the asymmetry of the posterior ends of the cerebral hemispheres is much less obtrusive than it is in most of the other groups. But in the cast of the brain case of the Rhodesian man the lunatic sulci are as nearly symmetrical as they are in the anthropoid apes. In the London skull, as I have already pointed out (this JOURNAL, November 7th, p. 854), the asymmetry is reversed (Fig. 2). In the course of the discussions this statement has excited I realized the fact, which had escaped my attention before, that the same type of reversal is found in the cast of the most primitive human brain case available for examination—that of *Pithecanthropus* (Fig. 3). In examining this cast a very large and distinct lunatic sulcus (L) is found upon the right hemisphere. On the left (S) it is so indistinct that its identity is doubtful, but the area behind it is much smaller and especially less prominent than that of the right side. As in the London skull, the superior longitudinal sinus turns in the normal way to the right side, but for the reasons which have already been given in the case of the London skull, there can be no doubt that this earliest known human being was also left-handed. The asymmetry of the occipital end of the brain affords corroboration of the view that *Pithecanthropus* was definitely a member of the human family. In other words, the asymmetry of the brain is as old as the human family itself, and is a fundamental character distinguishing man from all other members of the order Primates.

Attempts have been made in the past to determine whether extinct members of the human family were right- or left-

handed by a study of the implements made by these people. But so far as I am aware no one has attempted to solve the problem directly by a consideration of the fossil remains of man himself. The evidence of asymmetry of the brain to which I have called attention throws a light on this problem that is much more reliable than any inference which can be made from man's handiwork.

The question naturally suggests itself whether there is any trace of asymmetry in the anthropoid apes. It can be seen at a glance that although the two cerebral hemispheres in the anthropoid apes are approximately symmetrical and do not reveal the obtrusive asymmetry found in most human beings, the superior longitudinal sinus does not always split into branches of equal size as so frequently happens in the lower apes. In the gorilla, in particular, the sinus often turns to one or the other side, and there seems to be a slight preference for the right side, as in the case of the human sinus. Although there is no definite asymmetry in the brain, some interesting facts, collected by Graup from the writings of Mollison, von Bardeleben, and others, suggest the remarkable conclusion that the bones of the right arm are longer than those of the left arm in the gibbons and orangs (as in man), but the bones of the left arm are the longer in the chimpanzees and gorillas. These writers contrast this asymmetry in the anthropoid apes with the symmetrical condition found in the monkeys. Though there is no obvious asymmetry of the brain, there seems to be in the (apparently ambidextrous) anthropoid apes an instability that affects the symmetry of the limbs, although neither the right nor the left is so definitely selected as in the case of the vast majority of human beings.

Taking into consideration the fact that the cortical territory concerned in the causation of the lunatic sulcus is the visual area, it is of some interest to note that B. S. Parson, in his book *Left-handedness* (1924), came to the conclusion that the ocular dominance—that is, the use of one eye for fixation—determines both cerebral dominance and the "handedness" of the individual.

The apparent asymmetry of the visual cortex, that of the left side associated with the right field of vision appearing to be considerably bigger than the right, at one time deceived me into believing that the area striata was actually bigger on the left than on the right side. But careful measurement of this region in the two hemispheres ultimately convinced me that appearances were illusory, the apparent differences being due, not to the contrast between the visual areas of the two hemispheres, but to the mode of packing. The larger parietal area on the right hemisphere usually pushes back the area striata further than happens on the left†.

In all these discussions it must be remembered that even if the right- or left-handedness does not make its appearance until well on in the first year of life, it is due to congenital tendencies that manifest themselves at this relatively late time. It must also be remembered that these congenital tendencies may in many cases be overcome to a considerable extent by training, so that it is possible to get a brain showing the asymmetry distinctive of left-handedness with limbs which show the conditions usually associated with right-handedness.

* The reference to this observation is found in the Report on the Human Remains (p. 25) in the First Annual Report of the Archaeological Survey of Nubia for 1907-8, which was published at Cairo in 1910.

DISCUSSION ON
OPERATIVE TREATMENT OF CHRONIC
MIDDLE-EAR SUPPURATION

OPENING PAPERS

I.—GEORGE J. JENKINS, C.B.E., F.R.C.S.,

Aural Surgeon, King's College Hospital

It will be my endeavour briefly to put before you certain of my own experiences, and to suggest for the following discussion certain points which arise from them and from my study of the work of others on this subject.

In considering the operative treatment of chronic otorrhoea I understand that we have to regard the lesion causing the chronic discharge as one which cannot be affected by treatment of the nose, nasopharynx, or Eustachian tube, and which must be dealt with by operative treatment of the posterior part of the middle-ear tract. Operations in cases of chronic suppurative disease of the middle ear are undertaken primarily for the removal of the conditions which are potentially dangerous, and secondarily in order to get rid of an offensive state which often necessitates a good deal of care and daily attention, also, in some instances, with the possibility of improving the hearing.

It may be as well to review the whole situation in order that we may be clear as to the points of discussion. For many years the radical mastoid operation was considered the only one for cases of chronic otorrhoea, though Schwartz employed his method for chronic as well as for acute cases, no doubt with a certain amount of success. There were instances of chronic discharge in which the perforation was in the outer attic wall, the hearing being still good, and in these operation was delayed until there was evidence of danger in waiting any longer. In recent years many otologists in all parts of the world have been experimenting with methods that are something between the Schwartz and the radical mastoid and which have been termed "conservative mastoid" or "modified radical mastoid" operations. This endeavour to find something better than the radical mastoid operation must have arisen because the latter has been found to be insufficient or defective in some respects.

There can be no doubt that the ordinary procedure does effect the complete removal of the disease, and so puts the patient in a safe position, thus attaining the primary object. When the result is completely successful the ear is dry and comfortable, the hearing is maintained or even improved, and the ear requires no further attention, except that which in some cases arises from the recurrent accumulation of cerumen, etc.

In what, then, does the radical operation fail? The result is not always satisfactory. Sometimes the Eustachian tube in a patient, no matter how carefully this has been provided against. Often the hearing is damaged, and sometimes the ear requires careful attention for years, even when epithelialization has been quite satisfactory. If done for certain attic affections, the resulting loss of hearing may be very marked. Perhaps some members may discuss the possibilities of eliminating some of these defects, but it has been my experience that, even after taking all care, now and again I have been disappointed in some respect with the result in cases demanding this form of procedure.

The conservative or modified radical operation is an endeavour to improve the result of the radical mastoid, and I understand that the object of this discussion is to estimate the values of these various methods of dealing with chronic suppurative middle-ear disease, when the lesion

is primarily in the middle-ear tract behind the Eustachian tube. Whatever operation is done, the objects should be (1) to remove all foci of potential danger, (2) to retain the maximum hearing, and (3) to leave a state of affairs that will necessitate the least possible after-attention. Rapidity of healing should be a secondary consideration.

Any form of modified radical mastoid operation must satisfy these conditions, and in some direction give a result superior to the ordinary radical mastoid, or at any rate cause less disturbance to the patient as regards after-treatment. The ordinary radical mastoid operation removes possibly more than is necessary, in the modified operation our endeavour is to remove only as much as is necessary to attain our objects. To remove only what is necessary requires an accurate knowledge of the pathological condition and of the regional anatomy. The exact nature and situation of the disease are not, however, clear in every case. If we could be quite clear on these points, a good deal of doubt as to the correct procedure would disappear.

We all agree that, when investigating a case of chronic otorrhoea, we should try to discover the nature and situation of the lesion. It may be possible to do this in but a minority of cases, yet there is a broad classification which has been a help in the past in guiding us as to treatment and which still forms the main basis of the modified operation. It is as follows:

There is one group in which the hearing is good, almost as good as in a normal ear, in which, apparently, the mechanism of the middle ear has not been damaged. This group may be subdivided into three: (1) That in which the disease is more or less confined to the attic, though often the antrum is also involved, in these cases the perforation will be in the outer attic wall and in Shrapnell's membrane. (2) That in which the disease is mainly in the antrum and rudus, sometimes the posterior part of the tympanic cavity is involved, especially in the outer wall immediately behind the line of attachment of the tympanic membrane. In this the perforation is usually in the posterior segment and is at times entirely surrounded by membrane, though much more often part of the margin is bony, sometimes, however, it involves the whole drum, often the descending process of the malleus can be seen articulating in an apparently normal manner with the head of the stapes. (3) That in which there is a combination of the two conditions just mentioned. We are all familiar with this group, in which the middle ear deafness signs are very slight and yet the potentiality of danger is present. Often such patients apply for treatment because of some loss of hearing, which frequently can be corrected by inflation.

The second group includes those cases in which the middle-ear conducting apparatus has been involved. The hearing may be very bad, although at times, even with destruction of the descending process of the malleus, whisper may be heard at 18 feet. The perforation is similar to that found in subdivision (2) of the first group. In the cases there is usually no improvement with inflation, and the patient often volunteers the information that the hearing is better after syringing. At times the wool wick gives marked improvement. In the majority of these cases the descending process of the malleus has been partially destroyed and is commonly in a state of active caries. If the perforation is happily situated it may be possible to recognize the diseased condition of the malleus, although in a considerable number of instances there is no positive clinical evidence of this prior to operation. In the great majority of cases, however, in which a radical mastoid operation has been done for clinical reasons, disease of the malleus has been discovered.

A third group includes those cases in which there is evidence of a gross lesion of the wall of the labyrinth or of the labyrinth itself.

Granulations, polypi, and cholesteatomata may, of course, be found in any of these groups. It has been my practice when granulations and polypi are present not to attempt to classify the case until they have been removed or sufficiently reduced to enable me to come to a decision.

Without going into further detail of the clinical features and without considering the variations I think this rough classification, which has been of great use in the past, will

serve for the discussion of the problem before us. Before the modified operation had been considered all cases of the second group would have been dealt with by a complete radical mastoid operation, and perhaps it would be as well first of all to compare the results of this old and tried procedure with those of the modified operation about which there is so much discussion at the present time. It is in this group, in which the conducting apparatus has been damaged, that I have tried the modified radical mastoid operation about to be described, whenever a case presented itself which I thought was suitable. The special clinical features which constitute suitability are the presence of a small perforation entirely or almost entirely surrounded by membrane, and evidence that the incus has been damaged.

Altogether I have operated on 38 such cases in which I diagnosed that the incus had been partially destroyed. In two of these I found that I had removed a sound incus. In a great majority of the others the incus was in a state of active disease. When the hearing was very good I was naturally influenced in favour of an operation which should interfere with the middle-ear region less than would the radical mastoid, but otherwise hearing and hearing tests have not been a deciding factor.

I have preferred the radical operation when there were evidences of a gross lesion of the labyrinthine wall or indications that the labyrinth had been definitely involved, also when there was a large perforation of the tympanic membrane extending to the bony wall, and when cholesteatoma was present. Granulations have not been considered in absolute contradiction to the operation about to be described, but when present I have more commonly tried other forms of modified operation or the radical mastoid.

While considering how to remove the disease completely without interfering more than necessary with normal anatomical formation, I deemed to be present on one occasion when the incus was accidentally removed at a Schwartz operation for acute mastoiditis. The result following this operation was good, the membrane healed and the hearing was satisfactory. This led me to consider the application of the operation to cases of chronic otitis in which I thought the disease was confined to the antrum, aditus, and incus. It seemed probable that it would be a further improvement to obliterate the antrum and mastoid cavity by means of a flap of periosteum. By this procedure I hoped to follow the principles indicated above, believing that all the disease could be removed, that the perforation in the membrane would afford sufficient drainage until healing had occurred, and that the malleus would be only very slightly altered in form. The method is as follows.

A skin-deep incision is made a little behind the line for that of the radical operation, and extending a little lower. The skin is then undermined to the posterior margin of the mastoid and well forward as far as the anterior margin. A vertical incision is now made through the periosteum, almost on the anterior surface of the mastoid process, extending upwards to the supramental triangle. This should not be carried higher than necessary, as an important artery enters the base of the flap at this point. Another vertical incision is made through the periosteum at the posterior margin of the mastoid. A thin periosteum elevator is then passed under the flap from the posterior to the anterior incision, then the flap is separated upwards and downwards. Near the tip of the mastoid it is necessary to cut it away by means of a blunt tenotome. The posterior incision is extended upwards, curving somewhat forwards, and the separation of the flap completed. The flap can then be held upwards and forwards with a blunt-pointed retractor, care being taken to avoid bruising as much as possible. The next step is to open the antrum, and in such a case one has to go through dense bone (Cheatle's diploetic type) such as is always found in this class of case. I now proceed up to a certain point as in a radical mastoid operation, removing the bony external auditory meatus, and thoroughly cleaning out the antrum and aditus, but leaving a fine bridge and then I remove the incus through the aditus. The latter can often be done by a fine pair of forceps or by means of a small scoop. The upper edge of the mastoid cavity is neatly

rounded off so that the periosteal flap may not be in any way compressed when placed in position. The wound is now carefully cleaned, the ragged edges of the flap cut away, and all surfaces are smeared with a mixture of sterilized bismuth subnitrate and iodoform. The flap is carefully placed in the antrum, so that no part of it is in any way crushed, the wound being then closed except in the lower part, where a small wick impregnated with bismuth and iodoform is placed as a drain for forty-eight hours.

In many cases the wound has consolidated in a fortnight, though often the lower part has taken longer to heal. The principal difficulty I have encountered has been a fairly common forward lateral sinus, and I think that the defective healing of the lower part of the wound can be largely got over by removing a little of the outer surface of the lower part of the mastoid. You will see as an exhibit the incuses of these cases, and will note the disense of the descending process.

My object in removing the incus was, first, to eliminate what I considered to be an important focus of disease, which I did not think likely to clear up spontaneously, secondly, by its removal I thought that ample drainage would be provided for the antral region until healing had occurred. Many otologists have used a flap of periosteum in mastoid operations, my object was to occlude the antrum and mastoid cavity as soon as possible.

The results have not been quite so satisfactory as I expected. In many the perforation has persisted and in some remained moist, though the hearing has been good, often so much improved that the patient has been more than satisfied. The moist, or even dry, perforation implies a certain defect which must be regarded as a partial failure, and in some a radical operation has had to be done later. In all cases seen six months or more after the operation the posterior superior wall of the malleus was retracted as if the flap had shrunk, and the eardrum tissue had pulled the membranous meatal wall into the mastoid cavity.

Taking into account the consistent success in acute cases of the Schwartz operation, and having in mind the good result seen to follow accidental removal of the incus, I have been somewhat surprised that the method I have just described has not been more uniformly successful. In a few cases, however, the result has been perfect, the perforation in the tympanic membrane has closed, the malleus has returned in almost normal form, and the hearing has often been much improved.

It is remarkable how good the hearing may be after the extended Schwartz operation with removal of the incus, suggesting indeed, a further study of the function of the ossicles. The following is an example.

A man aged 56, underwent this operation on the left ear in May, 1924, and in April this year the condition was as follows: Perforation in left tympanic membrane closed by cicatrix adherent to the inner wall of tympanic cavity. Weber's test to the left side. Rinne's test right positive to all tones left negative to low tones—to about 256 d.v. Bone conduction (Fischmann fork) diminished in both ears about five seconds. Low tone limit right good left up to about 50 d.v. High tone limit (monochord) right by air 18 cm, by bone 17 cm left by air 22 cm, by bone 17 cm. Conversational voice left and right 24 ft +. Whisper right 24 ft +, left 21 ft +.

The extremely satisfactory results in some cases have led me to try this procedure a little too widely, but in those in which the margin of the perforation is formed entirely or almost entirely by membrane I certainly think that it ought to be tried. In cases unsuitable for this particular operation I have tried intratympanic drainage, with and without removal of the bridge and outer attic wall. In two instances where bone has formed a considerable margin of the perforation, indicating that probably the part of the outer wall of the tympanic cavity behind the line of attachment to the drum was diseased, I have employed a method similar to that described by Bunney. I used a periosteal flap, removed the bridge and outer attic wall, and also the bone forming the margin of the perforation, and the incus. In one case the ear ultimately dried up, in the other the ordinary radical operation had to be done. Later I came to the conclusion that these two cases did not show any advantage over the ordinary radical operation.

My experience of intrameatal drainage has been that, though the hearing in some cases has been well maintained or even improved, there has often been persistence of discharge which necessitated a radical mastoid operation. So often has this occurred that I have rather preferred the radical mastoid operation when the extended Schwartz operation with removal of the incus seemed unsuitable. If I had tried some form of meatal drainage operation in those cases in which I did the extended Schwartz it is probable that I should have had more satisfactory general results from this method, but it is my impression that I should not have obtained any results so perfect as those in some cases treated by the other method. The obvious difficulty in estimating the value of a given procedure is the absence of any control.

With regard to the operative treatment of the first group of cases, I endeavoured at a meeting of the British Medical Association in 1912 to show the value of the Schwartz operation in selected cases of chronic otorrhoea with good hearing and intact incus. Schwartz and others have employed this procedure when the disease seemed to be confined to the antrum and aditus. The operation I have adopted proceeds up to a certain point as described for cases in the second group.

When it has been diagnosed that the disease affects only the antrum and aditus, the operation terminates as a simple Schwartz, or, in one or two cases, has been extended so as to remove the outer wall of the aditus. This, of course, is the operation for acute mastoiditis, and it is also done in cases of persistent discharge following an acute middle-ear condition, and when the clinical features are such as indicated in group 1, subdivision (2). It is not common to find this type of case as a chronic otorrhoea of many years' standing, but when it does occur I do not think there can be any dispute as to the selection of the operation, as we should all agree that the simple Schwartz ought to be tried.

When the disease is in the attic the problem before us is obvious. Here we have a localized disease which frequently causes but slight disturbance of hearing, and it is clear that treatment for the removal of such disease must be carried out in such a way as to endanger the middle-ear apparatus as little as possible. We have all seen cases in which there has been considerable loss of the attic wall from disease, and yet the user involved has completely healed without operation. We have, moreover, seen perforations of the outer attic wall, with long standing discharge, heal soundly after no further interference than removal of a polypus. In all cases of this type in which healing occurs after local treatment only, it is my belief that the disease is confined to the outer part of the attic cavity. Where intrameatal treatment fails it is probable that the whole attic cavity and the antrum are affected. In the latter class of cases there is undoubtedly an element of potential danger which it is obviously the duty of the surgeon to endeavour to forestall. The practice of waiting for indications of danger and then performing a radical mastoid operation is open to criticism. It is clear that an operation that would ensure the same measure of safety as a radical mastoid, without at the same time endangering the hearing mechanism, would be one greatly to be preferred. In the paper read at the British Medical Association meeting in 1912 referred to above I described the extension of the Schwartz operation to include the removal of the outer wall of the aditus and attic in these cases. At that time I had done this on two patients. One of these I had under observation for about two years, and the result was completely satisfactory, the other was satisfactory whilst under observation, about six months. There is no doubt in my mind that this procedure ought to be adopted in this group of cases.

In group 3, where there is evidence of gross drainage to the outer wall of the labyrinth or to the labyrinth itself, I have preferred the old radical mastoid operation, and have not attempted any modification, as I have considered the free drainage afforded by this form of operation important for attaining the primary object of placing the patient out of danger. When I undertook to write this paper I had hopes that I should be able to describe to you the results of operations done some years ago, but I was dis-

appointed that out of the 38 cases in group 2 I had operated on only 15 have responded to my request to come to be examined. Of these only 4 were completely satisfactory in that the perforation in the membrana had closed. The remainder all had perforations persisting, with or without discharge. With regard to the remaining patients, I think it would be safe to say that many probably drifted into other hospitals for treatment, whilst others are probably so far satisfied with the result that they have not thought it necessary to come for treatment at all.

Having put before you as briefly as I could the details of my own experience and practice in the operative treatment of chronic otorrhoea, it now remains for me to fulfil the second object of my paper, and to indicate for your consideration certain points which have appeared to me important in the operative treatment of chronic middle-ear suppuration.

In the first place, perhaps, we ought to consider the clinical features that influence us in deciding on the type of operation in any given case. When the disease does not affect the ossicles, and the hearing is very good, as in group 1, there must be a strong leaning towards a Schwartz or extended Schwartz operation, though there may be doubt as to whether meatal or mastoid drainage should be adopted. It is when the disease has seriously affected the tympanic cavity and caused a certain damage to hearing that there will be a difference of opinion as to choice of operation. You are all familiar with the work of Hertz, Fraser, Barany, and others, and have, no doubt, tried the operative procedures described by them.

With many of us use of the modified operation has been directed by no definite governing principle. It has been a haphazard process, a series of experiments with different operative procedures of which the ultimate result has been, and still is, a matter of uncertainty. For example, some surgeons advocate simple drainage of the antrum by the meatal route in cases in which there is obvious disease in the tympanic cavity, whilst others in similar cases consider it advisable to remove the outer wall of the aditus or more.

What I have said in this paper will serve to indicate the principles that have guided me in the more or less experimental measures I have used for certain cases of chronic otorrhoea. I think it is on this matter that discussion is especially needed. We know that we cannot always diagnose the exact cause of the chronic otorrhoea, nor can we always be certain of the situation of a gross lesion. If we could say definitely that it was necessary or not to remove all gross disease in a given case, then we should have advanced a great deal. I personally attacked the problem with the idea that it was advisable on principle to remove all areas actively diseased. It is an important point to settle, because on this depends the question whether or no we should remove the outer wall of the aditus and the incus, or at any rate the incus. As I have said, it has been my practice to regard a partially destroyed incus as a probable retic focus, and I have usually removed it. That a dry ear may be obtained without removal of the incus we all know, but if the removal of the diseased incus does not jeopardize sound hearing, then I can not see why it should not be removed.

Another point for discussion is the importance of maintaining a more or less normal anatomical form of the external auditory meatus. Though it is as well to aim at maintaining the normal form as far as possible, yet I think that I, at any rate, have attached an undue value to this object. A very large mastoid cavity is certainly a disability and may be a constant source of trouble, it is, however, rarely necessary, seeing that this class of case, as pointed out by Mr. Cheate, always occurs in a dense mastoid.

Again, we ought to consider the importance of the persistence, after a modified radical operation, of any form of external communication with the middle-ear tract. We all know instances of a dry perforation of the tympanic membrana in patients who have not known that they have had ear trouble at all. We certainly should not think of interfering in such an ear, in which it is probable that the middle-ear tract is otherwise healthy. There is no doubt that a dry perforation of this type after a modified radical

operation may be looked upon in the same light. A persistent discharge of any kind, however, must be regarded as indicating an unhealthy condition and potential danger.

There may be some difference of opinion as to the effects of various surgical measures on the hearing. Some maintain that the hearing after the radical mastoid operation is rarely altered in a marked degree for the worse, and that it is often very much improved. In the absence of control it is difficult to decide one way or the other, but my impression is that the hearing is usually considerably better in a modified radical operation when it is completely successful, though it must be remembered that after a radical mastoid with the aid of a wool wick hearing is often all that can be desired.

The position at present seems to me to be as follows. In cases in group 1 where the tympanic cavity is not primarily affected some form of extended Schwartz operation should be adopted. Further experience is needed to enable us to decide which drainage route is the more satisfactory, though I am inclined to adopt the meatal flap and meatal drainage when the outer attic wall is removed, and post-meatal drainage when a simple Schwartz operation is done. When there is a serious affection of the tympanic cavity, and especially when the tympanic membrane is extensively destroyed, I do not think the results from any form of conservative operation are equal to or as good as those of the radical mastoid operation. Between these extremes there are cases in which the region of the tympanic cavity is affected to some extent, and many of these I consider suitable for some form of modified mastoid operation.

At present we cannot define the limits of any particular operation, but as our experience increases we shall probably be able to select cases with more certainty for this or that procedure. In the meantime, when we propose a modified operation we should be sure that the patient understands that the procedure may be unsatisfactory, and that the radical mastoid may have to be done after all.

When describing the treatment of the wound I mentioned that it was my custom to smear the surface with a mixture of sterilized bismuth and iodoform. I should like to add that care should be taken not to leave masses of this mixture in pockets—that the smear should be really a very thin layer over the various surfaces.

The thirty-eight incuses that I have put out for your inspection are from the cases from group 2 which I have operated on since 1920, and which form the basis of this paper. A diagnosis of damaged incus was made in these thirty-eight cases, in two a sound incus was removed. I should have stated definitely that the incus was removed by way of the antrum and aditus.

II—SYDNEY R. SCOTT, M.S., F.R.C.S.,

Aural Surgeon and Lecturer in Aural Surgery,
St. Bartholomew's Hospital

AN interchange of ideas based upon individual experiences should lead to the elucidation of at least some of the problems we have to face in endeavouring to save our patients from the disabilities caused by diseases of the ear. My own contribution is necessarily brief.

Let us first consider what are the features of chronic otitis media which affect the principles of treatment. Is measure of time—the duration of the disease—alone the special feature of chronic otitis media? No doubt we meet with suppurative otitis media of many months' duration where the changes in the tympanum and mastoid cells are indistinguishable from those met with in cases of otitis media of a very few weeks' duration. In the past we have been prompted by the dangers of otitis media to adopt operative treatment.

The immediate results of otitis media, both the intracranial complications, extracranial and intracranial, are common to acute cases of short duration as well as to cases of very long duration. The same is true of the cerebral complications, lepto meningitis and brain abscess, as well as infection of the lateral sinus. These complications are liable to arise at any stage of the disease—almost from the outset in some, and only after the disease has existed very many years in others. I myself have

removed an infected thrombus from the sigmoid sinus scarcely six days after the onset of a first attack of otitis media. Again, one has also had to open and drain a temporo-sphenoidal abscess within sixteen days of the onset of otitis media.

On the other hand, the dangers of fatal intracranial complications are not removed by the fact that no ear effects have been noticed in the course of the first few weeks, or during many years. Gray mentioned death from meningitis long after the patient believed himself immune to danger from middle-ear suppuration which had lasted for fifty years. No doubt many of us have seen parallel cases. Surgical technique has so far advanced that we are justified in the opinion that it is not fear of death from local complications alone that calls for operative measure. Loss of hearing, interference with social pleasures and duties, the remote ill effects on general health caused by ear suppuration, may necessitate operative treatment.

We now know that the sooner the onset of otitis media is recognized, and the earlier we incise the tympanic membrane and effectively drain the tympanum, the more frequently does normal resolution take place. Similarly, it is now accepted practice that where there are signs of retention in the mastoid we must open and drain the cells and antrum without awaiting evidence of the development of further mischief.

But what are we to do in those cases of tympanic discharge—chronic otitis media uncomplicated by pain or pyrexia or superficial signs of mastoid disease—that is, with no signs of retention? The acute symptoms of the first three or four weeks have passed off, the general health has recovered from the initial febrile disturbances, but the discharge does not cease for four, five, or six weeks, or as long as we care to wait. How long can we afford to wait for the discharge to cease, and hearing to return to normal, and what should be done? We have been taught never to forget Sir William Wilde's dictum, which referred, of course, to cases which had not been operated upon. Is his observation still true? "As long as discharge from the ear is present we can never know how, when, and where it may terminate, and to what it may lead." This truism dates back to the time of Hippocrates. Can we modify it, save only in those cases treated by the radical mastoid operation?

Personally I think it is impossible to lay down a constant time limit beyond which the continuation of otitis media, at first acute, must be called chronic, but it is certainly true that cases of otitis media where defective hearing and otorrhoea persist from the onset for more than four or six weeks up to periods of over nine months or longer should still be regarded as acute cases, and treated as such by what we call Schwartz's operation. In other words, chronicity of discharge alone does not necessitate any departure from our rule to perform Schwartz's operation and preserve the tympanum and ossicles—a principle of treatment laid down over a generation ago.

It is our experience that hearing returns to normal after Schwartz's operation in nearly every case operated upon early enough. If an operator finds that the hearing does not recover in a series of cases, he might inquire whether he has not unwittingly displaced the incus by inserting a seeker into the aditus to ascertain his bearings. It is certainly worth while paying special attention to this detail in technique in order to avoid risk of displacing the incus.

But between the earlier chronic cases of otitis media and those of long standing is a wide range of time during which destructive changes to the ossicles are more certain to take place. In an analysis of over 1,500 cases operated upon for middle ear disease at St. Bartholomew's Hospital we find that approximately in two out of three cases of very chronic middle ear disease no incus can be discovered at all, and the head of the malleus is then generally eroded. Not very rarely the malleus also has completely disappeared. In these cases of disorganised ossicles the surgeon has no cause for regret at having performed the radical operation, but it occasionally happens in chronic cases that the incus and malleus, after extraction, are found to be absolutely normal in themselves, though surrounded by granulations or swollen mucosa. As there appear to be no certain means of dis-

tinguishing these latter cases, a conservative course has been practised for many years. We have felt concerned that nothing short of removal had enabled us to discover the absence of destructive osteitis or arthritis, and it is certainly a matter worthy of the closest attention to endeavour to find some definite evidence of ossicular destruction before exposing or removing the auditory ossicles, or running the risk of breaking an intact ossicular chain. Where there is a definite cholesteatomatous formation in the antrum and aditus, the incus has almost certainly become disintegrated.

In a case open to doubt as to the necessity for extirpation of the tympanum, when there is no cholesteatoma and no labyrinth disease, even where hearing is very defective, it is certainly permissible to watch the effect of Schwartz's operation as modified by Kuster before advising recourse to the epitympanic operation or to the radical operation. Where it is definitely found that the tympanic suppuration persists in spite of satisfactory mastoid drainage and freedom of the nose and pharynx from infection, and that hope of recovering hearing must be given up, there are very few advocates of conservation of the tympanum.

Of our list of mastoid operations, Schwartz's operation, Kuster's operation, the "epi-tympano-mastoid" operation, and the "convection" operation, are far commoner than the original radical mastoid operation—perhaps because we operate earlier, but certainly because we attempt to discriminate among chronic cases, and endeavour to preserve the tympanum whenever feasible. For many years at St Bartholomew's Hospital we have recognized the advantages in operating *a deux temps*, on conservative principles. When, therefore, Mr Jenkins advocated removal of the incus, it seemed as if the teaching at King's College and St Bartholomew's Hospitals must be at variance, but Mr Jenkins has made it quite clear in his address that his procedure is not so much concerned with removing the incus as with conserving the malleus, tympanic membrane, and annulus tympanicus. His procedure is only applicable to certain chronic cases which otherwise might have submitted to the epi-tympano-mastoid, or perhaps to the radical mastoid operation. He has therefore systematized a new stage of conservatism, not a new stage of eradication, and I feel happy to say our doctrines are not at variance.

As regards the method of drainage in the radical operation, whether modified or not, complete closure of the posterior meatus is the general rule, after dividing the posterior meatal wall, and throwing the mastoid and tympanic cavities and external meatus into one common compartment, free from any subdivisions. We should, however, point out that this enlargement of the meatus is in no sense an essential part of the radical operation. Section of the posterior meatal wall, with consequent expansion of the meatus, is a recognized modification of Schwartz's operation. Such an expedient has been adopted to render the mastoid operation cavity accessible to inspection from the external auditory meatus. It is obvious that no flap can be fashioned from the meatus or concha alone to clothe the entire tympano-mastoid cavity, an up- or down-turned flap will cover only a portion of the surface of the operation cavity, the rest must heal by second intention—the formation of granulations followed by epidermization. This is often a slow process, which can be hastened by skin grafts applied at the same time—a procedure which we have practised for the last fifteen years.

salutary precautions which experience has taught us would prevent him from falling off the wall.

I imply that the best treatment of chronic suppurative otitis media is the thorough and courageous treatment of its almost invariable progenitor, acute suppurative otitis media, be the cause of this latter what it may. The ancient surgical principle, "*ubi pus ibi evacua*," applies here with more than its usual force owing to the intricate regional anatomy and to the serious loss of function and the vital risks which are countenanced by delay. The acutely inflamed middle-ear tract, which, in whole or in part, still suppurates at the end of from four to six weeks and in which oral, nasal, and nasopharyngeal sepsis has been adequately treated, is a middle ear which requires transanal drainage. I am convinced with McKenzie that when this fact is not only widely appreciated, but given practical recognition, and that when courage takes the place of procrastination in the treatment of the acute or subacute suppurating ear, the eventual necessity for the more mutilating and never quite satisfactory forms of aural surgery which are embraced by the term "radical mastoid operation" should rarely, if ever, arise.

We must constantly bear in mind that the absence of the classical clinical signs of mastoiditis in these acute cases serves in no wise to controvert the wisdom of early retro-auricular drainage. Their non-appearance should rather remind us of the probable existence of a sclerotic temporal bone—the infantile type of Chertle—and that in the absence of early and adequate drainage the likelihood of ultimate chronicity is increased.

Beyond the occasional successful application of the Schwartz operation to cases of questionable chronicity which appeared to justify this procedure, my experience of the conservative type of radical operation has been very limited. The fact that this experience was required whilst acting as Mr Heath's house-surgeon at the Golden Square Throat Hospital sixteen years ago may to some extent account for the scepticism with which I have since viewed all efforts to modify the classical operation of Zaufel. Mr Jenkins has impressed me by his thoughtful classification of the various pathological conditions which have to be differentiated in these cases, and by the ingenuity of his periotomy flap operation, but he has failed to satisfy me as to the *raison d'être* for a conservative operation in the vast majority of those cases requiring a radical operation. The older operation does, in fact, enable us to eliminate conditions which are potentially dangerous and an offensive state, and if the result is not always quite satisfactory, Mr Jenkins has been candid enough to admit that this also applies to the methods he has described. His contention that the modified operation is superior from the viewpoint of auditory function is the only attribute of this procedure which I consider worthy of serious consideration. But here again we lack definite comparative evidence with which to control results.

We are all aware of the occasional brilliant functional improvement which follows the complete radical operation. In my own practice I find there is an improvement in at least 75 per cent of cases, and that an actual deterioration in hearing is a very rare occurrence. I make a very determined effort to destroy the lining of the tube ostium and to open up any peritubal cells, but, apart from the removal of the ossicle remnants and any visible fungosities, I do not interfere with the tympanic mucosa. I strive to get as open and regular a bone cavity as possible. In carrying out the plastic operation I adopt the Y or T couched incision, the stem of the latter extending far into the concha, and I remove all the redundant cartilage and soft tissue. I invariably employ a primary skin graft in my uncomplicated cases, and am of opinion that this procedure (for which we are indebted to Billance, and after him to Marriage) marks the most decisive advance in the modern radical mastoid operation. The graft must be of sufficient length, breadth, and thinness. The art of obtaining such a graft will only come from much practical experience with a razor which is both sharp and heavy. I feel confident that those who have derived the manifold advantages of primary skin grafting the mastoid wound cannot have mastered the technical difficulties of cutting and applying

111.—J. BOWRING HORGAN, M.B., B.Ch., D.L.O.,

Laryngologist, North Charitable Infirmary, Cork.

I regret that I would not have the courage of a very strong conviction if I failed to preface the few remarks which I have to make upon the subject under discussion by a statement of my belief that in the overwhelming majority of cases the aural calamity which we designate by the name of "chronic suppurative otitis media" is a preventable calamity, and that the necessity of our devising a means of putting Humpty Dumpty together again could best be obviated by ruling ourselves of the timely and

then grafts. Marriage has claimed the following advantages for the primary graft:

- That the wound heals quicker
- That constriction and pouch formation do not occur
- That there is less after pain
- That it saves time and trouble
- That it shortens the period of the patient's absence from work
- That there is more probability of obtaining a closed tubal ostium

From an extended application of his method, with minor modifications, I am pleased to signify my whole-hearted concurrence in the reality of these advantages. I reckon upon a convalescent period of from six to eight weeks, and of a period of from two to three weeks' physical disability. In my shortest case the ear was dry on the eighteenth day, and I almost invariably find that, apart from the tube ostium, epidermization is complete between the fourth and the sixth weeks. The bugbear of the Eustachian orifice, though it still exists, does so in a much more amenable manner. As regards auditory function, I find that there is an improvement in at least 75 per cent of cases, and that a deterioration in hearing is so rare as hardly to merit recognition. I graft over an exposed lateral sinus or dura mater, but the loss of one case in which there existed a fistula of the external semicircular canal, from delayed suppurative labyrinthitis, would deter me from the future application of a graft in such cases.

I nick the graft in a dozen or more places with fine-pointed scissors after it has been transferred to the Ballance lifter. This has the advantage of permitting a ready exit to any air or fluid which lies beneath the transposed graft after it has been tamponaded home. I clean the cavity with salino and hydrogen peroxide, and temporarily apply fly artery forceps to any bleeding or oozing points in the soft tissues. Hemostasis and unimpaired vision are further secured by passing a thick length of ribbon gauze through the mental wound, the approximated ends of which are used by an assistant to pull the amide well forwards after the retractors are removed.

The graft having been floated on to the saline solution which fills the wound I carefully but forcibly repose it on to the bone surface with small pieces of gauze which have been squeezed out of saline solution. Three or four of these are sufficient. After they have been firmly pressed home with the finger for a minute or two they are picked out singly, a suitable probe being used to repose any part of the graft which tends to curl up or adhere to the gauze, if it has been properly pressed home this tendency is surprisingly slight. If the graft has been cut on what are necessarily extravagant lines, it will now be found that every part of the bone cavity is covered and that an ample tongue of graft is still available behind the wound. The gauze holding the amide forwards is now divided, and, working through a nasal speculum in the external meatus, the cavity is rapidly and completely filled with one-inch self-edged iodiform ribbon gauze, the redundant portion of the graft being brought forwards through the meatus so as to contain the gauze, pudding bag fashion, and to form a protective covering for the cut surface of the mental wound. Anybody who has performed the first post-operative dressing on a non-grafted and on a grafted case can appreciate the beneficence of this small manoeuvre.

I close the wound with Michel clips, taking special precautions to obliterate or, if this is not possible, to drain temporarily, the small cul-de-sac which is apt to remain between the graft and the posterior lip of the wound at its lower end. Failure to attend to this detail may lead to retention and wound sepsis after an initial and apparently satisfactory primary union.

The dressing which is applied to the thigh is of primary importance if the period of retention in hospital is not to be prolonged owing to a painful or unsatisfactory condition of the graft wound. After trying many forms of protective dressing I now cover the wounded surface with gauze saturated with final's balsam. This is retained securely by a bandage in which, to prevent the possibility of slipping strips of adhesive plaster are incorporated. This dressing is not removed for from two to three weeks,

by which time it will be found to have become loose and that re-epidermization is complete.

The first ear-dressing is performed on the fourth day, half the clips being then removed. In lightly refilling the cavity with ribbon gauze care is taken not to disturb the graft. The second and final dressing, with the removal of the remaining clips, takes place on the sixth or seventh day, and the patient is discharged from hospital using poroxido drops, to which spuit is subsequently added, on the ninth or tenth day. He is instructed to syringe the ear gently with sterilized salino solution at infrequent intervals, and to report for inspection every two weeks, but the wound cavity is in no way interfered with until at least six weeks have elapsed. All traumatism, however slight, tends to arrest epidermization. The repeated applications of gauze dressings, however aseptically made, are not only painful, but by their adherence to the raw surfaces must be looked upon as a source of trauma and of microbial dissemination, and, in consequence, as a retarding factor in the process of cicatrization.

Of the difficulties attending the pre-grafting methods of after-treatment, Luc has truly written: "Les plus beaux résultats appartiennent, non pas aux plus brillants opérateurs, mais à ceux qui ont apporté le plus de soin, de méthode, de patience et de précautions antiseptiques dans leurs pansements consécutifs."

By the successful application of the primary skin graft we virtually hand over to Nature this most difficult part of the surgical treatment of these cases, which, therefore, need no longer be a menace to the skill of the aurist or to the endurance of his patient.

GENERAL DISCUSSION

Mr J. ALDINGTON GINN (Maidstone) said he did not intend to discuss the papers of the openers of the subject under debate. His point was that, having discovered that a form of chronicity was present and that local treatment had failed, it was necessary to decide upon an operation which was conservative of hearing and would at the same time put out of court any area of potential trouble. His hospital supplied him with fifty or sixty mastoid operations a year. Recently he had adopted as a conservative measure the transmastoid atticotomy of Bondy, as practised by Sourdis and others in France. The outer wall of the attic was removed, and the roof of the bony meatus also to the tympanic ring. The mastoid antrum, with removal of the bridge, being at the same time freely opened, the ossicles were exposed and could be inspected. A large flap was cut, including the superior and posterior wall, and all dressings were done through the meatus. He was glad to have so experienced an authority as Mr Sydney Scott in agreement, and so far he was satisfied with his results. His object was to elicit the opinion of others who might have had more experience of this method. The hearing was retained and usually improved, it was certainly never worse.

Sir JAMES DUNDAS GRANT (London) said that among the operations for chronic suppurative disease of the middle ear the claims of the operation of ossiculectomy had been generally overlooked. Apart from other considerations, the ossicles often acted as a barrier, damming up the discharges and desquamative accumulations which might form in quantity in the attic even when the antrum and mastoid cells were only very slightly involved. He could quote cases of this nature presenting the most violent symptoms, in the form of headache, giddiness, and even epileptiform seizures, in which a radical mastoid operation appeared to be called for, but in which the symptoms entirely subsided after the removal of the ossicles and without further surgical intervention. The patients had lived and were enjoying good health, many with most useful hearing. For the extraction of the incus he found Hoffmann's curette (procureable from Meyer and Phelps) the most reliable instrument for this the most delicate part of the operation. Another principle worthy of application in the case of post-suppurative "cholesteatoma" was the wide exposure of the cavity by free removal of the overlying bone and the retention of the living membrane if found to be smooth,

shiny, homogeneous, and fairly adherent. It did not penetrate, as was once supposed, into the Eustachian canals. He had found the after-treatment greatly shortened by allowing this matrix to act as "skin graft." He would like to lay stress on the fact that persistence of discharge after the radical operation was due to catarrhal processes in the Eustachian tube. A closure of the tube was desirable, but in the absence of this much might be done by means of treatment of the nasopharynx and the injection of astringents through the tube. The timely adoption of this method of treatment had even brought about a cure in a patient for whom the radical operation had been considered indispensable.

Dr W S SYME (Glasgow) said that the first essential in dealing with chronic middle-ear suppuration—and by "chronic" he understood not necessarily a suppuration of long standing, but one which had passed beyond the acute stage—was, as Mr Jenkins had so well discussed, a very thorough examination so as to define the actual limit of the disease in the middle ear, bearing in mind that they now had other operative measures less severe than the radical mastoid procedure, and yet applicable to certain cases. Another point was that they could now recommend the performance of a conservative operation at a much earlier period in well defined cases where previously they had hesitated to advise the radical mastoid operation, always with the condition, as both Mr Jenkins and Mr Scott had insisted on, that they should give the patient to understand that a more extensive operation might later be required.

Mr H NORMAN BARNETT (Bath) believed that a conservative method of operating on the mastoid region was strongly indicated, he was doubtful if complete obliteration of all the hearing apparatus of the middle ear was justified, except in rare cases. It was, he conceived, the duty of the aurist to preserve hearing, and the danger arising from leaving the structures of the middle ear was, he thought, greatly exaggerated. The mastoid antrum was, in his experience, involved at an early date. Acute middle ear disease was an eminently curable condition, and if under observation and careful treatment it had not been cured in four to six weeks the case had become one in which, he believed, the mastoid area was involved. It had been his rule to advise operation and to open up the mastoid antrum if such treatment had proved ineffective. In no case had he found the antrum unaffected, and in many cases the disease had been far advanced, involving a large amount of bone. The procedure he now adopted was to make an incision immediately behind the ear, rather than further back, to make a periosteal flap, and clear out the antrum and all the mastoid cells down to the tip, to remove the bridge, except a small portion at the bottom, and leave intact the tympanic ring. The middle ear was then washed out from the antrum, with drainage through the meatus. A large opening was made in the posterior soft wall of the meatus, and the periosteal flap was attached to the junction of the opening. Drainage was effected through a large tube passed into the antrum, resting on the remains of the posterior bony wall. The posterior wound was entirely closed, and the subsequent treatment, which aimed at curing the diseased condition of the middle ear which might remain, was carried out through the antrum. The antrum gradually healed up with granulation tissue, and, the tube being removed, the incision in the posterior soft wall became obliterated and the meatus more or less normal. The result of many of these cases had been entirely satisfactory, but in others the result had not been so good. In his opinion, the question of whether the tympanic membrane healed was largely a matter of age rather than disease, and in many cases where it did not heal no trouble seemed to supervene, except that the hearing was not so good as it might be. He believed that when the attitude of the aurist was towards conservative methods of treatment the public would consent to a much earlier operation as they could be informed that the hearing could be improved, and in most cases very largely so, or even made normal. It was not his experience that the hearing, after a radical opera-

tion, was good, being in many cases entirely absent. In addition to this the condition of many cases after the complete operation was often unsatisfactory from the surgical standpoint, and also from recreation of cerumen and debris, and he had been frequently asked to see cases in which there was a septic condition underlying this accumulation. He supposed all of them had a string of such cases that came to them periodically. In his opinion, removal of the middle-ear hearing apparatus was unsatisfactory, frequently from the surgical standpoint, always from the functional standpoint, and hence was not to be advised. Lines of investigation by undoubtedly along those of modification of such an operation, with a view to leaving the person undeformed and with the function improved, or perhaps restored. He would plead very earnestly for an early exploration of the mastoid antrum in any case, as it was quite useless ordering drops to a person with chronic discharge. That in itself was bad, and it was high time that the textbooks reformed their methods of describing the indications for opening up the mastoid. With the exception of acute mastoiditis, no satisfactory indication was given. The fact that was placed in drops for long standing middle ear suppuration was deplorable, and there was no question that there were a very large number of persons in the community who were being given drops for disease of the mastoid. He hoped the general members of the profession would realize more and more that middle-ear disease with discharge from the ears was a very serious condition, and should not be treated on lines that they would never dream of applying to general surgical conditions.

Mr G J JENKINS, replying, said that he should have mentioned that Staacke described an operation in 1911, which included the removal of the meus, followed by sound healing of the tympanic membrane. When he started this communication he was tempted to make an historical survey of the works of men who had directed their attention more particularly to modified radical operation, but he had come to the conclusion that his audience would probably be more interested in a procedure that had been tried sporadically in 1913-14 and more seriously since 1920. It was impossible in the time allowed to deal with both. He was sorry also, that time did not permit a more detailed description of the clinical features which had influenced him in deciding what operative procedure to adopt in any particular class of case.

DISCUSSION ON CHRONIC NON-SUPPURATIVE MIDDLE-EAR DEAFNESS (EXCLUDING OTO-SCLEROSIS)

OPENING PAPERS

I.—SIR WILLIAM MILLIGAN, M.D.,
Formerly Lecturer on Diseases of the Throat and Ear, University
of Manchester Consulting Aurist and Laryngologist,
Manchester Royal Infirmary

TREATMENT OF CHRONIC CATARRHAL OTITIS MEDIA

How to treat chronic catarrhal otitis media in its advanced stages with any degree of success is a problem still unsolved. Like the hardy annual, this subject crops up year by year at one or other society or assembly of otologists, and, like the hardy annual, little or no change is to be noted as years roll on. While otology has made great strides during the past quarter of a century, more especially in the treatment of suppurative disease in and around the middle and internal ears, the treatment of chronic catarrhal and oto-sclerotic lesions remains practically at a standstill. The object of today's discussion is to ask ourselves why this is so, and, if possible, to hear suggestions as to new avenues of investigation which may lead to some definite advance in the treatment of this affection, the *bête noire* of otologists.

To be perfectly candid and to lay all my cards on the table at once, I must acknowledge that, so far as my experience goes, advanced chronic catarrhal otitis media is an incurable disease, and one in which all we can hope to do in our present state of knowledge is to endeavour to stem its

progress and to prepare the patient for the advent of a severe degree of loss of hearing.

If we admit that in advanced chronic catarrhal otitis media anything approaching a cure is out of the question, our aim should be to endeavor (1) to prevent the onset of the disease, and (2) to treat it energetically in its early stages, so as to prevent, if possible, the advent of incurable fibroid changes. To what are catarrhal changes in the middle ear due? In a large percentage of cases it will be found on close investigation that the commencement of the disease dates back to childhood or early adult life as the result of some such ailment as measles, scarlet fever, or purulent nasal catarrh. It is extraordinarily how frequently, on *post-mortem* examination, a glairy yellowish fluid is found in the middle ears of young children dying from various diseases, a fluid comparable to and containing the same organisms as those found in mucopurulent nasal catarrh. My contention is that this minor sepsis in the middle ears, in extremely frequent and often unnoticed complication—in a sense a latent otitis—is the starting point of many, if not most, of the genuinely chronic cases of middle ear catarrh we see in later life.

Sepsis is in many cases, I believe, the underlying element in the production of those pathological changes which ultimately lead to the connective tissue and atrophic alterations we associate with chronic catarrhal otitis media. In a purely catarrhal or inflammatory condition the natural resisting powers of our tissues are able to deal with the situation, and to induce a *restitutio ad integrum*, whereas in cases with a septic basis submucous changes ensue which lead to atrophic alterations in the mucous glands and to the ultimate formation of fibrous tissue in the tubo-tympanic axis, changes which tend to become progressive and permanent. The deduction I draw is that all cases of catarrhal otitis media accompanied by sepsis require a much longer supervision than is usually accorded if the disastrous effects of subsequent pathological changes are to be nullified.

To an audience such as this it is quite unnecessary to recapitulate the importance and the necessity of the removal of tonsils and adenoids and other forms of nasal obstruction and nasal sepsis. What is necessary to emphasize, however, is the necessity of keeping up, in cases of otitis media, for varying periods a careful toilet of the mucosa. It is the lurking sepsis from small foci of infection which keeps the fire aglow, which lights up with every catarrhal attack, and which induces the deposition of fresh fibrous tissue. Between what we recognize as a strictly catarrhal lesion and what we recognize as a mild septic lesion there is a very thin line of demarcation. Given certain extraneous conditions, the one almost imperceptibly slides off into the other. For this reason I hold that any exudation into the tympanic cavity should be got rid of at once by paracentesis and inflation. It is the exudation which is likely to get infected—infected, it is true, often with organisms of slight virulence, but infected sufficiently to be the means of inducing deeper-seated changes. To drain the tympanic cavity is doing nothing more than obeying one of the first rules of surgery. Exudation into the pleural or peritoneal cavity is removed by tapping; why not drain a middle ear, a far more delicate part of the human frame? The exudation it is true, is only the objective indication of an existing catarrhal infection and if removed promptly enables resolution to take place rapidly. If left, as in my experience it so often is, it hopes that it will absorb, it is irritative, liable to become infected and to act as a mechanical block clogging the ossicular joints and leading to subsequent adhesions.

The researches of George and Chads Dick go to show that in cases of scarlet fever an antitoxin is obtained, as the result of subcutaneously injecting horses with a sterile scarlet fever toxin, and injected on the first day of the appearance of the rash no ear complications are found to take place. Should this observation be confirmed by other workers an important advance in prophylactic treatment will be accomplished. Possibly also a similar antitoxin will be found to be of use in measles, a prolific factor in the production of chronic catarrhal deafness.

As main that sepsis does play an important part in the production of chronic catarrhal changes, it may be that our

attention should be more riveted on the bacteriological aspects of the initial phases of the disease.

The sheet anchor of treatment is unquestionably inflation, either by means of the bag or the Eustachian catheter, repeated as frequently as the particular case demands. The more the improvement after inflation and the longer it lasts, the better the prognosis, because the more superficial are the pathological changes. Conversely the less the improvement and the shorter the period of improvement, the deeper and more organized are the changes. The existence, however, of a genuinely stenosed Eustachian tube calls for a preliminary course of bougieing. I have little belief in the efficacy of bougieing through the pharyngeal orifice of the tube in cases of severe stenosis, it is manipulative surgery in the dark. To be effective it should be done through the tympanic orifice after a preliminary paracentesis, and preferably under a general anesthetic. For this purpose fine silver bougies are very convenient. The bougie, smeared with bipp, should be retained *in situ* for an hour or two or even longer in order that the mechanical effect of its presence may have time to assert itself. The irritation produced is practically nil, and even a slight reaction appears to have no prejudicial effect, rather the reverse. The injection of vapours or fluids—oil, alkali, or digestive—into the middle ear through a tube, even if any reasonable quantity ever reaches its destination, is, I believe, practically useless, any beneficial effect appearing to me to be due rather to the column of air entering the middle ear than to the effects of the fluid employed. Intimympanic operations, once so popular and highly acclaimed, have been tried and have been found wanting, and rightly so, because their performance was based on an imperfect appreciation of pathological facts.

The crux of the problem is that we have to deal with a slowly organizing sclerosis of the connective tissue of the middle ear cleft and with a destruction of its normal lymphoid tissue, due, I believe, originally to a septic infection not sufficient to produce suppuration, but sufficient to produce hyperplastic changes in its mesoblastic elements, progressive in character and mechanically destructive to the normal physiological function of the organ. Much of existing treatment is, to my mind, provocative rather than curative, and not in the best interests of the patient, while no known treatment has more than a temporary effect. It is true that the progress of the disease may become arrested for varying periods, if not altogether, but, speaking generally, the loss of hearing, gradual in most cases, is slow but certain.

The fact that the membrane is more or less opaque or more or less retracted has little to do with the amount of the existing deafness. High grades of obstructive deafness are found where the membrane is hardly altered in appearance, and where there is little, if any, retraction. The vulnerable area is the inner wall of the middle ear, the region of the stapedio-vestibular articulation and the region of the round window, and perhaps more especially of the latter. That this is so is proved not only by microscopic examination of the middle ear in chronic cases, but also as the result of experimental surgery. On microscopic examination the mucosa of the inner wall will be found to be more infiltrated by newly formed connective tissue than any other portion of the middle ear, with corresponding interference with the function of the all important fenestrae.

Many years ago I tried in several cases the effect of performing a radical mastoid operation in cases of advanced chronic otitis media. The thickened membrane, the malleus, and the incus were removed, sometimes ankylosed, but more frequently not, and the inner tympanic wall freely exposed. For a few days, sometimes for a few weeks, and in a few cases, there was undoubtedly some slight improvement, but it was in all cases of short duration, and the final result eminently disappointing. At the same time, mobilization of the stapes was attempted, but also without benefit. To keep the cavity in anything approaching an aseptic condition is naturally difficult, and whether it was due to a slight superadded sepsis or to the post-operative disorganization of the middle ear, the results were so discouraging, as not to warrant repetition.

One of the first effects of the sclerosing process in the middle ear is the destruction of the mucous glands, which are found almost entirely in and around the tympanic orifice of the tube. When the droplets of secretion which normally lie in the fossula rotunda are not forthcoming as the result of this atrophy, an important aid to sound conduction is at once missing.

Investigation leads me to regard with great respect the region of the round window. It is in this neighbourhood that connective tissue changes are not only most active, but are also of most importance, for as the round window becomes more and more obliterated so does the sense of hearing become less acute. Middle-ear deafness with paracusis means that the principal pathological changes are going on in and around the foot-plate of the stapes, middle-ear deafness without paracusis that similar changes are going on in the region of the round window.

A blocked round window is inimical to good hearing. Whatever may be the function of the saccus endolymphaticus, whether it acts as a safety-valve or not, I am of opinion that the membrane covering the round window responds to every sound stimulus transmitted through the stapedio-vestibular articulation, and that its free mobility is essential to good hearing.

An important factor in chronic middle ear deafness is the subconscious loss of acuity of the cortical centres of hearing. We are all familiar with the statements made by patients of periods—transient it is true—of good hearing, and we are equally aware that sounds in one's own immediate neighbourhood have often no effect upon our auditory centres if we are otherwise mentally engaged. In cases of chronic catarrhal otitis media where the lower tones of the scale are gradually becoming less and less appreciated a condition of auditory lethargy is induced which results in a general atony of the cortical centres for hearing. That these centres are capable of some amount of re-education, I think, made clear by the work recently carried out by Dr Cathcart, and whether more attention should not be given to re-education as a matter of routine treatment, whether by means of the electrophonoide method or some other method, is, I think, at least worthy of discussion.

The tinnitus which is so often present in these cases is sometimes even more distressing to the patient than the actual deafness. Very severe and persistent tinnitus indicates probably a superadded oto-sclerotic process. Unfortunately, we have no means of diagnosing a peripheral from a central tinnitus, and as it is often toxic in origin the prospects of getting rid of it are by no means bright. Large doses of hydriobromic acid appear at times to have some effect. In very severe cases I have from time to time attempted to remove the stapes, but it is just in these cases that the stapes refuses to be removed on account of its fixation to the margins of the oval window. When very persistent and the cause of severe mental depression, and if accompanied by a high grade of deafness, a complete removal of the cochlea, although not free from risk, is justifiable, but very seldom entirely successful. Attention to the state of the general health is, of course, essential, and residence in a dry, bracing, and high district is advisable if it is possible.

To sum up my experience I venture to say

- 1 That clinically two types of catarrhal deafness should be recognized—the one a purely evanescent catarrhal process, the other a catarrhal process, with an accompanying mild and creeping sepsis.
- 2 That the presence of creeping sepsis is the underlying factor in the establishment of chronicity.
- 3 That maintenance of the patency of the Eustachian tube is the most important factor in treatment.
- 4 That to effect this all obstructive or septic lesions in the throat, nose, and nasopharynx should be carefully eliminated.
- 5 That repeated examination and short courses of treatment are essential if the best results are to be obtained.
- 6 That re-education of the auditory centres should be systematized, and if possible, simplified.
- 7 That the main hope of preventing the onset of chronic

middle-ear deafness lies in the early recognition and treatment of catarrhal and septic changes in the upper respiratory tract.

II—J KERR LOVE, M.D., FRF.P.S.,

Consulting Aural Surgeon, Glasgow Royal Infirmary.

THE treatment of chronic non-suppurative middle-ear deafness may be made as broad as the Atlantic or as narrow as the Avon at Bristol. Were I to catalogue the forms of treatment which have been tried and discarded during the past fifty years you would be as anxious to reach port as any of you have ever been to see the tall buildings of New York. Were I to name those on which otologists are agreed to be valuable I could do it in the time you would take to cross the Avon. That means that we are dealing with an affection in which the prognosis is bad, the treatment generally futile, or, at least, that cure is very rare. I am speaking of chronic middle-ear deafness as including two groups of cases—the cicatricial or adhesive group and the oto-sclerosis group, in which both changes predominate. Strictly speaking, as I see from the reference, it is the deafness arising from these conditions we are to discuss, and it is because I have something to say on this strict respect of the subject that I accepted your invitation to come here at all. I have also something to say about the prevention of this nearly incurable condition. The mechanical and operative treatment of chronic adhesive deafness has been, and no doubt will be, dealt with by other speakers, personally I have not had great success with these cases.

We are dealing with cicatricial tissue which tends to contract and cause fixation of mobile structures. We cannot remove it by operation without great risk of doing more harm than good. By ventilation of the middle ear and by massage through the external auditory canal we may stretch it and get slight improvement, but the contraction tends to recur. By laryngo and operation in the nose we may remove a cause which has been too long in operation to permit removal of the effects—namely, the deafness, and we may arrest the progress of the deafness, but we cannot cure in a really chronic case. Whether we like it or not, therefore, we otologists have to confess that we are seldom able to cure. Apart from treating tinnitus and attending to the nose, about all there is left for us is to make the most of residual hearing. Putting aside in the meantime the older "aids," such as ear trumpets and hearing tubes, and the most important "aid" of all, I mean lip reading, is there any movement in progress which holds out any hope that the otologist, aided by the physicist, may in time do for the ear what the ophthalmologist and the optician do for the eye?

Here let me draw an analogy or a parallel. An optician succeeds in correcting, by the help of a lens, almost any refraction error so long as the latter is not complicated by a disease of the optic nerve or its expression in the retina. He is able to influence rays of light before they enter the eye so that the distorted media in the eye focus the object on the retina. Why should the reconstruction not do the same with sound waves—say, of those of the human voice? The latter, like a light beam, is compound, consisting of a prime and upper partials. Do not carry the analogy too far. Sound can be reflected and refracted, I do not want to do either, but I ought to be able to reinforce the whole or any part of it. Physicists can do this, and it is in this direction that hope for the case of middle-ear deafness seems greatest. By a series of tubes and condensers, such as are used in wireless apparatus, one is able to reinforce the prime or lower tone of a human voice and leave the upper partials untouched, and, conversely, one may reinforce the upper partials and leave the prime untouched. The former is known as low-pass and the latter as high-pass amplification. The instrument by which this is done is made by the Western Electric Company of New York and the most recent form of it with which I am acquainted is called the "audio amplifier," and is described by Dr Isaac Jones and Professor Knudsen of Los Angeles. I cannot show you this instrument, but I can show you the wiring diagram, and you should be able to make it. All this looks very well on paper. With a

sound auditory nerve one should be able to do for a case of middle ear deafness what the optician does for a refraction error in which the optic nerves are intact, and yet it does not work out in practice. We cannot fit our patients with auditory spectacles—a term you may permit me to use for want of a better—as the optician does with lenses in refraction errors. Why is this? Let me give you Professor Kuudsen's answer.

Our experience with hard of hearing patients indicates that selective amplification does not fulfil our initial high anticipations. It is possible that through a process of adaptation the individual has become accustomed to associating various images of his real world in terms of the distorted sounds he has perceived. Therefore when selective amplification is provided to restore hearing to the normal or approximately normal condition these sounds really seem distorted to the individual.

I venture on another explanation of the difficulty. It is well known to otologists that, in a given case, whilst the signs of middle-ear deafness predominate—namely, the nose is out of order, the membrane is retracted or thickened—the patient perhaps hears better in a noise, Rinne's test is negative, and yet the tuning forks do not come out quite right. We have no difficulty, in the main, in saying that the case is one of middle ear deafness, and yet we cannot acquit the cochlea. We are dealing, in short, with a case of mixed deafness, and there are more cases of mixed deafness than we are accustomed to suppose. Our attempts to fit auditory spectacles are like the optician's when he tries to deal with a refraction error in which a retinal defect exists.

The following table illustrates the present-day position with regard to aids to hearing (electric).

No.	Division of Cochlea Stimulated	Type of Amplification	Result of Stimulation
8102 4690 2018	Area of very high voices and higher overtones	High pass amplification	A few successes in internal ear deafness
1024 512	Area of high voices and medium overtones	Equal amplification throughout the scale gives increased loudness with out greater distinctness	
512 256 128	Ordinary speech area	Low pass amplification	A good many successes in middle ear deafness

Shall we ever be able to write a prescription for what I have called, for want of a better word, "auditory spectacles"? Will the aurist send the patient to the acoustician with specific directions such as the ophthalmologist sends to the optician? If we do not it will not be the acoustician's fault. He can refract and reflect sound, reinforce it at any pitch to almost any extent, transmute it into electrical movement and retransmute it into sound. We aurists should therefore know the acoustical side of the problem, a knowledge which few of us have bothered about. It is not enough to send the patient to a salesman of "aids to hearing," hoping that the latter will do something. The real difficulty is that the acoustician waits on the aurist. The latter does not know enough of the pathology of the different types of deafness, the acoustician, of course, knows less. It is possible that because of the mixture of types the fitting of auditory spectacles may never be the success which the lens is in the hands of the optician. It is too early in the inquiry to say, but we shall not give up without further trial. When success comes the early instruments will be heavy and clumsy. But that need not worry us, the expert will get over that just as he got over heavy spectacles, bulky clinical thermometers, and ponderous motor cars. One consideration should encourage us—the acoustician need not be so accurate as the optician. The latter must focus accurately, because any inaccuracy means a blurred image and failure, the former has only to reinforce a particular zone of sound, usually the lower zone, and let the rest alone. If he succeeds he will get some success in middle-ear cases and he must be a bold man who, in view of recent progress in electrophonics, would set a limit to this.

I cannot conclude without saying something about the prevention of deafness. If it be true, and I think it is, that most of the chronic deafness of adult life is due to

neglected nasal and post-nasal disease in childhood, the next generation should be a better hearing people than we are. I am heartily in sympathy with all that is being done for the nose and throat as well as for the ear during the school period.

With regard to operations on the nose and throat for the cure of chronic non-suppurative deafness, I am always reminded of a remark by our Swiss colleague, the late Professor Rohrer of Zurich, who attended the Manchester meeting in the nineties of last century. Speaking of the restoration of hearing by such operations he said, "Gentlemen, you should always do these operations with a grain of salt." The faulty English gave force to the remark. The remark is still true, but great strides have been made since then in nasal surgery, and it is generally worth doing these operations for the benefit they confer on the nose itself and on the general health of the patient. Further, it is not unreasonable to believe that by them we may arrest a deafness which we cannot cure.

III—NEIL MACLAY, M.B., C.M.,

Honorary Surgeon, Throat and Ear Hospital, Newcastle-on-Tyne. After the exhaustive and lucid exposition which has been given by Sir William Milligan there seems little to add, and, indeed, little to say which might not be considered as reiteration. The subject, however, is of such importance, and is beset with so much that is difficult and obscure, that even a slightly different point of view or method of exposition may prove suggestive or helpful.

The treatment of chronic non-suppurative middle-ear deafness may with advantage be considered from two standpoints—preventive and curative—and the former must of necessity be regarded as the more important.

Preventive treatment implies an enlightened public opinion in the first place. People must be taught to give as much care and consideration to their ears as they mostly give to their eyes. There must be an end to the haphazard dropping of oils, etc., into the ears, as well as the purposeless syringing of the eus. It cannot be too widely known that such treatment may be harmful as well as useless, and that no treatment should precede intelligent aural examination.

The history of many deaf cases too often reveals intervals of months or years when symptoms have been slight and during which no attempt has been made at investigation, nothing, indeed, has been done save some ill advised efforts to remove non-existent cerumen. Instructional propaganda should reach the public through the medium of the practitioners of medicine. If the patient finds that his doctor makes a careful examination before giving advice, he will not as a rule be slow to grasp the importance of being in earnest about the condition of his ears.

Chronic middle ear deafness not infrequently owes its origin to the inflammatory changes which take place in early life and are associated with the presence of tonsils and post-nasal adenoids. Operative removal of the tonsils and adenoids in a certain proportion of cases restores the middle ear to a normal condition, but it must be admitted that there are a considerable number of cases in which this happy issue is not achieved, and a certain amount of deafness persists and becomes aggravated later in life. In some of these cases operation has been too long delayed, and in most of them the restoration of the middle-ear function should have been assisted by Politzer inflation as well as general or systemic treatment.

One would therefore include the efficient treatment of catarrhal deafness in early life among the more important means of preventing chronic non-suppurative middle-ear deafness. To be efficient, this treatment should be carried out as early as possible, and it should, as a rule, mean more than the removal of tonsils and adenoids. Many of these young people who are gradually, and it may be rapidly, laying down the foundations of chronic deafness need more than local or direct treatment.

It is generally admitted that the condition of the mucous membrane determines the conducting activity of the middle ear, and for this reason most of our routine treatment is planned with a view to improving the health and function of the mucosa of the middle-ear cleft. Unhappily, this treatment is for the most part purely local and direct,

and makes no provision for dealing with those systemic influences which we know disturb the mucosa and cause catarrhal attack, which is not amenable to local treatment.

That the health of the middle ear depends very largely upon the condition of the nose and throat as well as the mouth no one will readily deny. If, therefore, we can keep the mouth clean and entirely free from dental sepsis, and at the same time maintain normal conditions in the nose and throat, we have gone a long way towards the prevention of middle-ear changes likely to produce deafness.

When we come to consider the scope of the curative treatment of middle-ear deafness we so readily become conscious of our limitations and failures that we hesitate to employ the term "cure" in this connection. The means at our disposal which we may describe as belonging to the curative category suggest measures which are direct and indirect in their action.

Of the many remedies which are to be found in the direct classification the following are probably the most important: (1) inflation, (2) tympanic massage, (3) re-educative exercises.

Inflation, particularly with the aid of the Eustachian catheter, is a valuable remedial agent when used with discretion, it not only ventilates the tympanum and thus promotes healthier action of the mucosa, it also combats to some extent the formation of intra-tympanic adhesions. The introduction of medicaments into the Eustachian tube and middle-ear cavity is of very doubtful value, and, indeed, may prove distinctly harmful by causing reactionary swelling of the mucous membrane. A similar criticism may be levelled at the operative treatment and topical applications made to the pharyngeal end of the Eustachian tube. The Eustachian bougie is of questionable value unless we regard a very temporary improvement in hearing as a desirable achievement.

Pneumatic massage may prove helpful as an adjunct to other measures, particularly in those cases in which chronic inflammatory changes have given rise to the formation of adhesions in the middle-ear cavity.

Methods of re-education can fairly claim a certain amount of success. This line of treatment not only reawakens functionally dormant hearing, it also presumably fulfils the purposes of a massage. Re-education may be carried out by the Zund-Burguet apparatus, in which an electrical current operating upon an artificial larynx produces sounds which closely imitate the human voice in its entire range. This intricate electrical mechanism is unfortunately too costly to make its general use practicable, and a very large number of deaf people must, I fear, be content with less ambitious measures.

It seems possible to convey the human voice itself to the deaf ear by a less costly and complicated method, by employing an ordinary conversation tube, amplified, if necessary, by a receiver of large dimensions. With such an instrument the patient can read aloud to himself or be spoken to at intervals during each day, and the duration of the exercises can be arranged to suit the individual case.

The indirect treatment of chronic middle-ear deafness embraces all those measures, operative and non-operative, which aim at restoring the mouth, nose, and throat to a healthy condition. It may mean the removal of an unsuspected mass of adenoid tissue in the adult or tonsils which have hitherto been regarded as harmless. In like manner the diseased nasal accessory sinus or the structural deformity in the nose may call for surgical intervention, and the result justify the means adopted. Unfortunately there are cases which do not respond to those operations, and one must guard against undue optimism in regard to the prognosis.

The importance of dental sepsis, however trivial it may seem, cannot be exaggerated, and its efficient treatment should never be omitted.

In a proportion of cases thyroid insufficiency should be considered, and treated if necessary, if this defect proves to be the root cause of the deafness the administration of thyroid extract will invariably bring about a satisfactory result.

That the mucous membrane of the nasopharynx may be affected by systemic or blood-borne agents there can be no reasonable doubt. Toxic elements from the intestinal canal

or elsewhere, as well as a variety of biochemical products, may play an important part in the production of catarrhal changes which must inevitably influence the condition of the middle ear and impair its function.

For this reason no treatment planned for the relief of chronic middle-ear deafness should be considered complete which has not been preceded by a general survey of the patient. Above all things, intestinal toxæmia merits the most careful consideration. Treatment of this all too prevalent condition of the bowel will not infrequently mitigate or arrest the distressing tinnitus, and, in the earlier stages of the ear disease, it may materially assist in retarding the progress of deafness.

IV—H. NORMAN BARNETT, F.R.C.S. Ed., Surgeon to the Bath Ear, Nose, and Throat Hospital

I was much interested in one point of Sir William Milligan's paper, and that was his statement upon the re-education of the higher centres in deaf people, and his reference to the fact that they do not appreciate and interpret sounds which they actually hear. This is my experience, and I think it is an important point, although I do not think it is by any means a main point in the treatment of these cases.

I was sorry to learn from the paper of the pessimism of Sir William Milligan with regard to the treatment of the cases, I am glad to say I do not share this feeling. I believe that there is a distinct entity which we may call chronic dry middle-ear catarrh, perhaps for lack of a better designation, and this condition is, in my opinion, quite distinct from oto-sclerosis. The main sign of such cases is, I think, the pronounced lack of hearing all air borne sounds, though there may in certain cases be an admixture of nerve deafness or of oto-sclerosis. The Eustachian tubes are, as a rule, quite clear, although in some cases the condition may have spread to them from the middle ear, or vice versa. The appearance of the tympanic membrane differs—in some cases being perfectly normal, in some cases being retracted or thickened, and in other cases thinned. In such cases there is frequently a septic focus or a deformity in the nose and throat, such as septo tonsils, deflected septum, or enlarged or degenerated turbinates. Such conditions should, of course, be remedied before other treatment is employed, and in many cases the improvement is fairly marked, but in no circumstances should the case be left at that juncture and the patient dismissed from supervision. It is now, when the road has been cleared, that the treatment will be most effective.

My main lines of such treatment are the vaporization of the middle ear, through the Eustachian catheter, with a mixture of warm iodine and camphor vapour. Here I may say that I do not agree with Sir William Milligan that it is doubtful if the vapour reaches the middle ear, results, I think, contraindicate this view. The other main line is ionization, which is of vast importance in obtaining good results. I believe it is essential that the dose should be small to begin with, and the time limited. The following are the details of this part of the treatment.

The current must be from the main batteries or useless. Electromagnets tell us there is distinct difference in the two. The negative electrode (size about 3 by 2½ inches) is applied behind the ears over the mastoid area on a pad of but sixteen layers thick, soaked in a 2 to 4 per cent solution of potassium iodide. The positive electrode (size about 7 by 5 inches) is placed over a pad of the same thickness soaked in sodium chloride and placed under the hands. The electrodes and pads should be bandaged firmly. The current started very gradually, indication of tolerance being reached when the patient feels something—perhaps giddiness or a prickling heat behind the ears or a salt taste in the mouth.

The current used will vary with the individual. Some patients I find, never get beyond 5 ma. but 10 ma. is about the average. Exceptional pronounced cases may go up to 20 ma. with advantage but on the whole I am in favour of the current being fairly low as better results are usually obtained.

With regard to time, if there is no contraindication in the patient's condition the application should be made for fifteen minutes. It is very important that the time should not be long as in most cases where it is giddiness is experienced.

At times in very obstinate cases the electrodes are reversed, the positive pole being put behind the ear and the negative in the hand. In this case sodium salicylate is used in stead of potassium iodide.

The negative pole stimulates and excites and promotes vasomotor dilatation, the positive pole depletes and soothes irritable nerve endings.

The number of applications should be ten, administered every other day in the patient's skin can stand it. After that I give a little rest and go on for another ten, administered every other day.

It is difficult to assign relative importance to either of the lines of treatment. In some cases one has found that ionization alone has produced marked results when efficiently carried out, in other cases the treatment by means of the iodine and camphor vapour through the Eustachian catheter has been successful to a point without the ionization. I have no doubt, however, that in the majority of cases the combined treatment gives the best results.

A subsidiary point of treatment, but of importance, is the application of otomassage to the tympanic membranes where there is any suspicion of there being adhesions between the ossicles owing to the exudate in the middle ear.

The length of treatment should be a minimum of twenty consecutive treatments given daily, the ionization, as already stated, being given every other day. Some will take longer than this, some shorter, but as a rule it is not worth carrying out this type of treatment unless the patient submits himself or herself to it for a prolonged course. Even where the case is one of otosclerosis it has been my experience that there is combined with it middle-ear catarrh which if it is relieved will help the patient considerably.

The result of such treatment has been very satisfactory in my hands cases varying in age from 95 to 9 years having been seen. In all cases benefit has resulted, and in many restoration to normal, or nearly normal, hearing. I hope this afternoon to show some results of treatment on varying types as to age and as to intensity.

There are certain patients who, while not showing any signs of otosclerosis, yet do not seem to react as well as others. I take it that what happens here is that there are some structural alterations in the middle ear which are too advanced for regeneration, but such patients can be markedly relieved—to such an extent that they may be able to carry on their occupation in life in comparative comfort. To give one example. A schoolmaster was dismissed on account of his hearing interfering with his efficiency. He came to me, and, after treatment, he was reinstated by the Board of Education and has carried on ever since. This case, amongst others, I hope to show in order to emphasize the fact that such cases are capable of improvement and therefore should be treated, even if they still remain rather deaf.

It is very important that we should give a pronouncement to the public about deafness. They complain that they are met with the assertion that nothing can be done. They are drifting into the hands of the quacks, who are extremely active in our midst, both being no exception. That deafness can be cured is flamboyantly set before us on all occasions by those who prey upon the public.

I believe this to be true of the majority of cases, excluding otosclerosis and nerve deafness, which are, in my opinion and experience, rare as compared with dry middle-ear catarrhal deafness, and I would entreat the profession generally to believe that such deafness can be cured, and not to allow patients to drift on into the tragic condition in which they are walled in by the terrible affliction of almost total deafness. I would also urge the aural surgeon to labour at such cases with faith in the methods that he adopts and with an optimistic attitude towards the cure that will be effected.

Finally, in this meeting of the Section does nothing else than ventilate the fact that we do not regard deafness as a hopeless malady, but are determined that those afflicted shall be rescued from the hands of the quacks, who batten upon their ill-gotten gains—very often received from those wholly unable to afford the expenditure—then we shall not have met in vain.

GENERAL DISCUSSION

DR C. C. CATHART (London) mentioned a method of treatment of chronic middle-ear deafness which, undescribedly he thought, had not yet gained the favour of the medical profession in general. This method of so-called re-education of the hearing was carried out by the electrophonoids of Zund Burguet. He was aware that some eminent otologists as Dr Albert Gray, Dr Dan M. Kerrin and Mr Muscke had pronounced against it, though without much experience or it, and the profession did not seem content to follow their lead. His personal experience did not coincide with theirs, and in his opinion the electrophonoid treatment was one of the greatest recent advances in otological therapeutics, although it had the

disadvantage of being rather a troublesome one for the aurist to carry out properly. The treatment consisted in vibration of the tympanic membrane, vaso-dilatation of the vessels of the tympanic membrane and the middle ear, and stimulation of the nerve endings in the internal ear, the vibrations being conveyed to the ear by vibrating ear-pieces reproducing the sound vibrations of the whole range of the human voice. He did not profess to be able to understand the precise process of repair in the ear which occurred after treatment. He attributed the improvement mainly to stimulation of the organ of Corti and of the cochlear auditory centres, though there might be some local vaso-dilatation as well. But he did not think he was alone in not fully understanding the pathology of chronic otitis media. In order to find out the value of this treatment and also to obviate the fallacy that might exist by using other methods of treatment at the same time, he took 100 patients and treated them by the Zund Burguet method only. He felt justified, therefore, in stating that any benefit that had accrued to them must be due to that method, and that method alone. Every one of these 100 patients before coming to him had consulted two or more otologists of recognized standing, and many had consulted four or five, not only in Harley Street and the suburbs thereof, but in the provinces and abroad, in every case the deafness had been pronounced to be impossible of alleviation. As the deafness was chronic and progressive, the improvement obtained after a full course of the treatment lasted only six to nine months, and in order to keep up the improvement another course was required later. Sometimes, however, he had known the improvement to continue for one or two years without further treatment. The usual course of treatment consisted of thirty sittings, but as, unfortunately, one could not say beforehand whether it would be successful or not, it was necessary to give a preliminary course of twelve treatments. If considerable improvement occurred it was worth while giving a full course, if there was no improvement it was not.

His group of 100 patients came under three headings—namely, (1) 33 suffering from chronic otitis media, (2) 34 from nerve deafness, and (3) 33 from otosclerosis. He proposed to deal only with those suffering from chronic otitis media. In this group of 33 patients, 22 improved, comprising 10 males, whose ages ranged from 7 to 63, and 12 females, whose ages ranged from 22 to 60, 11, consisting of 5 males of ages 29 to 58, and 6 females, aged from 25 to 60, did not improve, and the treatment was not continued. One case had been advised to go to a school for the deaf and dumb, but after treatment he was able to go to an ordinary public school. Three cases were sent to him by Sir Charles Brillance, some years before he had performed a radical mastoid operation, with grafting, on the right ear in one and on the left ear in the others. The first and second could hear better in the operated ear, after treatment, than in the other ear. Of the total number of his published cases, 68 per cent definitely improved after treatment, and this included 67 per cent of the cases of chronic otitis media. He submitted that his results showed that the electrophonoid method of treatment, when properly carried out, afforded the most substantial advance in the treatment of chronic progressive deafness of recent years, and that it deserved more serious consideration from otologists than it had hitherto received.

SIR JAMES DUNDAS-GRANT (London) pointed out that in cases of non-suppurative middle-ear deafness the chief abnormalities were narrowing of the Eustachian tube with its results and the adhesive or proliferative processes caused by acute inflammatory conditions, often forgotten, in very early life, and—as Sir William Milligan had pointed out—very probably latent. Treatment through the Eustachian tube, therefore, took the first place, Sir James was in the habit of using a long-beaked catheter, through which he passed a fairly large gum-elastic intratympanic tube to act as a bougie as far as it would penetrate and as a catheter for the injection of an oil or drop of paroline or colloidal argemum. He was convinced that many cases escaped benefit through the imperfect introduction of the Eustachian catheter, among the chief difficulties was that of circumventing an oblique ascending spur or deflection

with the catheter introduced in the usual way. To meet this difficulty the catheter had to be inverted so that its beak lay on the floor of the meatus under the deflection, in a position analogous to that of the head of a golf-club. It was first pushed backwards into the nasopharynx and then turned downwards. From the striking improvement and from the sound suggesting the separation of adhesions, it was sometimes quite obvious that the tympanum was fully inflated for the first time, even in a long-standing case. In the intervals the patient might keep up the treatment for himself by the use of some form of self-inflator containing a few drops of diluted chloroform. It was an old observation that an charged with chloroform vapour passed through the Eustachian tubes much more easily than simple air. Intiatympanic operations were seldom of any value, but occasionally it was possible to break down adhesions by suction with a very powerful Siegel speculum or by severing the bands resulting from former acute inflammation. In a recent case in which there was a band uniting the short process of the malleus with the head of the stapes, division of this band was followed by astounding improvement in the hearing, so that the patient, who was previously so deaf that her family hardly took the trouble of speaking to her, became able to control and guide the family conversation. Such a case was, however, most exceptional. Sir William Milligan's observation that paracusis was present with immobility of the stapes while it was absent in rigidity of the membrane of the fenestra rotunda was most interesting, and might be explained by the fact that the fenestra ovalis was associated with the middle ear and so interfered with the hearing of deep tones, such as those in a railway carriage, which were inaudible to the sufferer from chronic middle-ear disease, while the hearing speaker raised his voice. On the other hand, the fenestra rotunda was in close relation with the delicate structures of the base of the cochlea and interfered with the hearing of the high-pitched tones rather than the lower ones. In looking over 100 consecutive cases of chronic catarrh of the middle ear and serositis he found

Simple chronic middle ear catarrh (uncomplicated)	49
Chronic middle ear catarrh (combined with serositis)	14
Chronic middle ear catarrh (combined with nerve deafness)	23
Chronic middle-ear catarrh (combined with identity of suppurative inflammation)	5
Serositis (uncomplicated)	6
Serositis (complicated with nerve deafness)	3

Improvement after inflation occurred in 92 cases, and in 21 of these it was very marked, showing the incidence of narrowing of the Eustachian tubes. Marked relaxation of the membrane was noted in 5 uncomplicated cases, and Sir James Dundas-Grant considered this as one of the results of long-standing Eustachian obstruction. He thought it was often overlooked. He had frequently encouraged patients' friends to re-educate them by repeating to them sounds, vowels, syllables, and words, but it was difficult to get them to keep this up. He had not felt encouraged to give much trial to galvanism, but at the present time he had a case of most extreme deafness in which, under treatment by galvanism, the capacity for hearing shouted sounds had been recovered.

Dr W. S. Sime (Glasgow) said that the prevention of adhesive processes in the tympanum was a more important matter than the treatment of these changes when they had occurred. That meant, as Sir William Milligan had pointed out, the careful elimination of conditions of obstruction and sepsis in the nose and throat, and especially, he was convinced, of sepsis. He was of opinion, in this connection, that nasal accessory sinus disease was much more common than is generally supposed, and, moreover, that tonsillar disease was still too frequently overlooked, because a thorough examination was so often neglected. Regarding the treatment of established cases of so-called dry catarrh of the middle ear pathological conditions in the mouth, throat and nose should be dealt with, though they could not in most instances, promise the patient that this would result in improvement to the hearing. In some cases,

however, there would be a quicker perception of sound, though the usual tests usually employed might not show it. He had been in the habit of making an application of silver nitrate solution to the Eustachian tube, sometimes with the aid of Yarnier's speculum. He asked Sir William Milligan if he had had no bad effects from paracentesis and downward bougienage. It seemed to him that there was a danger of stirring up a septic condition in the tympanum.

Mr HERBERT TILLEY (London) was of the opinion that the early stages of chronic adhesive otitis were frequently overlooked, and even by otologists. Possibly this was because the deafness was slight and varied much in its degree, and was often temporarily relieved by auto-inflation of the tympanum. Not infrequently the chief symptoms were a "woolly" feeling in the ear and an occasional "crackling noise." If the suture employed in ventilation tube at the same time as the tympanum was inflated the serious exudation could be detected by moist crackling sounds similar to those heard when advanced emphysema was present in pulmonary tuberculosis. Paracentesis should be carried out in such circumstances, and repeated if necessary—namely, if the incision healed and the fluid collected again. If the exudate was allowed to remain it tended to become gummy, and possibly later on it favoured the organization of connective tissue bands and adhesions. He could assure Mr Sime that no septic intratympanic complications need be feared if the meatus were carefully sterilized before making the tympanic membrane. If and when the serous fluid repeatedly recurred after paracentesis, the surgeon should be careful to exclude the presence of a new growth in the lateral wall of the nasopharynx. Of this type of antral complication he had seen eleven cases, and all of them in adult males. In the usual type of serous exudation into the tympanum it was his practice to inject through the Eustachian catheter a few drops of aigrol (10 per cent) after having removed the catarrhal fluid by inflation and aspiration by means of a Siegel's speculum. The fact that the silver preparation often passed into the meatus through the incision in the membrane amply proved that fluids could be injected into the tympanum by way of the Eustachian tube. He had satisfied himself that there was a definite, although limited, field for the useful employment of endocrine therapy in certain cases of chronic otitis media, and more particularly in females about the time of the menopause.

Mr SYDNEY SCOTT (London) said that he had never seen any real improvement in hearing that could be attributed to the Zund-Bugnet method alone. He had stress on Dr Neil MacLay's suggestion that where re-education methods were sought for the speaking tube and the patient's own voice possessed obvious advantages over any electrical method of producing artificial sounds. Another point in relation to deafness was dental sepsis, but he found that many dentists and patients and medical advisers regarded the examination of the buccal cavity and teeth margin as sufficient to decide whether there was evidence of dental sepsis. Mr Scott considered x-ray examination could not be dispensed with in discovering most cases. Those who insisted on trying electrical treatment could avoid giddiness by stimulating both sides equally with anode and cathode.

Sir WILLIAM MILLIGAN replying to the various points raised, said that he had endeavoured to avoid details and to take a broad and comprehensive outlook. Despite all that had been said he still maintained that preventive treatment was the main essential, and that when chronic catarrhal otitis media was in full bloom little or nothing could be done for it. He agreed with Sir James Dundas-Grant that the maintenance of the patency of the Eustachian tube was all-important and that the normal physiological functions of the middle ear were dependent on its efficient ventilation. The method of bougienage, he had suggested although more complicated, was much more effective than bougienage in the drill, and, moreover, had the merit of not damaging the lining of the Eustachian tube. He considered re-education of the sense of hearing of value, but thought that more might be done by re-education with the human voice.

DEMONSTRATION

[illegible]

Mr Barnett then showed a group of cases of chronic middle ear suppuration

Mr Barnett then showed a group of

middle ear suppuration

The first case was that of a highly skilled woman teacher who had a history of a very old standing discharge with pain, discomfort, and marked deafness going back into early childhood, she had had various treatments and had been ordered within a comparatively recent date to use drops. At an operation, however, extensive bone disease was found extending in all directions, She durly mator and the lateral sinus both having to be stripped, made an uninterrupted recovery though it was extended period tured, the hearing began to improve, and after function This of five years ago and there had been no untoward event since. The left side was also operated upon as active disease was but the double mastoid operation was not considered necessary. On treatment this ear cleared up so far as the child concerned, though the patient still largely depended on the right of operation for her hearing which required to be good for her work. Had a radical operation been performed her career would have been ruined and there would have been destruction of the function.

The next case was that of a highly specialized school teacher who in April 1924 for erratic and ill defined but not limited to the mastoid region. There was no discharge with temporary benefit but with tympany symptomage.

[illegible]

in spite of his diabetic history the membrane healed, his hearing was very fair, and he was relieved of all his symptoms.

The fourth patient had undergone a modified radical operation on both sides with extensive trouble was found, both tympanic membranes healed soundly. All symptoms were immediately relieved by the operation. Her tonsils were removed subsequent to as they were giving rise to special interest owing to long standing mastoid trouble, and the much done, and extensive bone disease.

The fifth case was of an ordinary sign of any particular pressure pain without any of the impaired health of the patient. The conservative operation was done, and the tympanic membrane found with considerable destruction of the tympanic membrane. After operation everything proceeded satisfactorily, though the patient was not a good one constitutionally.

Patients 6 and 7 were two boys with long standing otitis from the ear, marked deafness, considerable pain and other symptoms. In both cases the modified operation was done with treatment. No trouble had occurred in these cases since the operation.

No 8 represented a common type at the hospital—a persistent discharge from the ear—in this case a short period of treatment and a short recovery was slow and prolonged. Four years after operation.

[illegible]

Mr Norman Barnett added that these ten cases of turning
ago, circumstance, mentality, and length of onset were
instructive, and in his view presented a fairly complete
picture of the advantage of the modified operation. So he
were not quite so satisfactory, but those he had shown
emphasized (1) the absence frequently of any symptom but
persistent discharge, (2) the extensive trouble found, (3) the
futility of any treatment but operation, (4) the preservation
of function

ASCARIS IN THE BILE DUCTS

A FULL account of the case here described was forwarded to the BRITISH MEDICAL JOURNAL early this year, but was unfortunately lost in the post. As I feel that such a case should be placed on record, I am writing these short notes from memory.

The patient, a male, aged about 40, was admitted to the St. Peter's Hospital, London, on 15th July 1901, complaining of intestinal obstruction. He was jaundiced and had a very bad general condition. No history could be obtained from him. He was constructed by Dr. Theobald, and was found to be very large. The bladder was very large and contained a large amount of urine. The rectum was empty. The small intestine was found to be obstructed. The obstruction was found to be due to the presence of a large mass of Ascaris in the bile ducts. The mass was found to be composed of many small, white, thread-like worms. The mass was removed by the use of a large syringe. The patient recovered and was discharged on 1st August 1901.

A Chittagonian male aged about 40, was admitted to the
 Hospital suffering from intestinal obstruction. He was jaundiced
 and his condition extremely bad. No history could be obtained

CONGENITAL MALFORMATION OF SPINE

THE photograph reproduced herewith illustrates a case of considerable interest. The mother fell downstairs at the fifth month of a normal gestation, and although bruised and severely shaken was quite well again in two or three days. No doctor was called in. Labour came on in due course at full time, it commenced at 11 p.m. on one day and terminated at 2 p.m. on the next day. There was no difficulty in birth, and forceps and chloroform were not needed.

I was called in after the birth of the child as the back appeared to be malformed. I found that about the middle of the back there was a wound $1\frac{1}{2}$ in long and $\frac{3}{4}$ in wide on the right side of the spinal processes, no bone

could be felt in this wound, where it seemed to be entirely absent. Below the wound was a raised lump, which was hard, and felt like fused bone. It extended for about $1\frac{1}{2}$ in below the wound, and was about $1\frac{1}{2}$ in wide. There was a complete cleft palate also, but no hare-lip. The left parietal bone was about half as well developed as the right, and the right side of the frontal bone was half as well developed as the left. All the sutures were very wide, and there was a haematoma over the left parietal bone. There was practically no neck, it appeared to have been telescoped into the chest, which in front showed no marked abnormality.

The child, a girl, lived for fourteen days, and the photograph was taken after death. During life the baby never closed its eyes by night or day. The needles in the photograph were placed to show the upper and lower margins of the wound. A post-mortem examination was refused.

RECTAL ANAESTHESIA

IN the issue of September 19th (p. 518) Mr. Gianville Chapman and Mr. McLellan reported a case of rectal etherization. During the past two years I have operated on 125 cases in a home under rectal etherization. This represents 75 per cent. of the total surgical cases during that period, and I am convinced of the many advantages it offers over administration by inhalation. Amongst these are the ease of administration, the absence of apprehension on the part of the patient, the absence of coughing, itching, and staining, so frequent when the anaesthetist is not expert, the reduction of shock, and the absence of post-operative vomiting. The method I now employ is as follows.

If the patient be at all nervous she is given bromide for a day or two before operation, an enema is administered the night before operating, and the bowel is washed out three or four hours before operation, one and a quarter hours prior to operation a hypodermic injection of hyosine compound B is given, and half an hour afterwards a mixture of 51 oz. of ether and 2 oz. of olive oil is introduced into the rectum with catheter and funnel, immediately before introducing this mixture 1 oz. of olive oil is run into the rectum, this prevents the burning sensation of which most patients complain. The catheter is then pushed in a little further and the ether and olive oil mixture run in slowly, the administration taking about twenty minutes. The patient is then allowed to lie quietly for half an hour. In a few cases (those in which the amount of ether had been reduced to 4 oz.) it was necessary to supplement the anaesthesia for a short time with warm ether given by Shipway's

apparatus. After the operation the bowel is freely irrigated with warm saline, and 2 to 4 oz. of olive oil left in the rectum.

It is interesting to note the wide field of utility for this form of anaesthesia. The series of 125 cases includes hysterectomy, gastro-enterostomy, gall stones, fixation of kidney, tonsils and adenoids, resection of nasal septum, dental extraction, perineorrhaphy, operation for haemorrhoids.

In three elderly people, who were so frightened that it was deemed advisable not to let them know when the operation was to take place, the administration has been carried out without the slightest knowledge on the part of the patient.

R D LAURIE

SEROUS SUTURE MATERIAL AND PEPTIC
ULCER

RECENTLY it has been stated that diminution in the incidence of jejunal ulcer following gastro-enterostomy may be obtained by the sole employment of catgut in suture of the mucous and serous coats. In thirty years' personal experience of this particular operation, in which catgut has been exclusively used for suture of mucous layer and silk for serous, I have not had, to my knowledge, a single case of peptic ulcer to record. Such an occurrence can only be attributed to maladroit introduction of the external (serous) continuous silk suture, if any unabsorbable suture material is allowed to embrace the mucous coat an ulcer must follow.

The object of this note is to draw attention to the fact that while absorbable catgut is essential for approximation of divided mucous membrane, its employment for any serous closure is fraught with danger of dehiscence. Having had two deaths after enterectomy from such use of catgut, I have no compunction in warning surgeons as to the tragedy which, sooner or later, will attend the use of such unreliable material for serous union.

In gastro-enterostomy, as in eutelectomy, the employment of Lembert (serous) silk stays to guide the introduction of the continuous Lembert (serous) silk suture is, to my mind, the only certain method of avoiding a mucous lesion. I have found that the durability of catgut based on superficial tests is a false index when it is exposed to the action of the peritoneal juice.

Many years ago Professor Kocher said that "silk is the only reliable material for suture of any serous wound," and my experience dictates that the teaching of that distinguished surgeon is correct. I have never used clamping lions,² as I have always considered them inappropriate.

Buenos Aires

JOHN O'CONNOR, K.B.E., M.D.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

EAST YORK DIVISION

A CLINICAL meeting of the East York Division was held in the Hull Royal Infirmary on November 20th, with Dr S E DENYER in the chair, when a series of interesting cases were shown.

Dr R J BARLEE showed

- (1) A case of large double inguinal hernia with hydrocele in a man aged 35. It had developed shortly after the onset of venereal disease and had been ascribed by the patient to this disease.
- (2) A case of tumour of the testis. The patient had an injury to the testis when he was a boy and the swelling increased in size while he was in the army. This he ascribed to riding.

In the discussion Mr J F GILL described a case he had seen which had been diagnosed as haematoma, but which at the operation was found to be sarcoma. This, he thought, should make one look with suspicion on a haematoma in this situation.

Dr DENYER showed two cases

The first was a case of gastric infection secondary to abscess of the teeth in a woman, aged 35, with chronic epigastric pain coming

¹ Lancet, October 2th 1912.

² BRIT. MEDICAL JOURN., 1 February 25th, 1922.

on two hours after food, nausea, vomiting which relieved pain, and slight haematemesis three months ago. The teeth and gums were pale, and x-ray examination of the jaw showed septic roots in both upper and lower jaws and a root abscess in upper jaw. Nothing abnormal was found in the stomach by the x-rays and the blood films were normal. After the teeth had been extracted the patient improved markedly and put on 3 lb in one week.

The second was a case of narcolepsy. A girl, aged 19, of good physique and previously healthy, when 16 years of age began to have attacks of sleepiness from four to nine times a day. At a meal or other time she would fall forward asleep would sleep for a few minutes and then awake quite fresh and without headache. All her systems were healthy, but she was emotionally contentious and after sleeping at work would work harder than before so that her employer should not suffer loss. The points in diagnosing her condition were from (1) Epilepsy—the sleep was too long and there was no after headache. (2) France—the sleep was too short. (3) Cataplexy—no flexibilitas cerea. (4) Encephalitis lethargica—no diplopia and no moral change or Parkinsonism. (5) African sleeping sickness—she had never been abroad. (6) Catatonic form of dementia praecox—there was no mental change and no flexibilitas cerea. The treatment was nitroglycerin and caffeine.

In the discussion on this case, Dr F. C. EVE described a case he had seen of a similar nature, and commented on the functional element of Dr Denyer's case, which contrasted with his own case where the patient, who was a man, developed the condition after overwork.

Dr RICHARD ROBERTS showed a case of cancer of the left tonsil, and a case of sarcoma of the posterior pillar of the fauces. These two cases brought out the contrast between the typical ulcerated cancer and the round smooth swelling of sarcoma.

Dr TURRO showed a case of Addison's disease which had been treated by small doses of suprarenal extract. There had been marked pigmentation, but it had all disappeared except a slight amount on the back and a patch on the roof of the mouth.

In the discussion, Dr J. NELSON, raising the question of diagnosis between tuberculosis and tumour of the suprarenals, recalled two cases of malignant disease of the gland. Dr EVE mentioned that pigmentation was not an invariable symptom of Addison's disease, and mentioned a case he had seen where there was only very low blood pressure but no pigmentation anywhere. At the post-mortem examination typical tuberculosis of the suprarenals was found.

Dr TURRO showed also a case of lymphadenoma treated by x-rays.

The patient had been admitted a month before with discrete enlarged glands on the left side of the neck, and a mass of glands in the axillae and groins. The right leg was swollen and the left leg had commenced to swell several times. Nothing abnormal was found in the abdomen. The blood picture was normal except for an eosinophilia of 6 per cent. Diagnosis was confirmed by the histological picture of one of the glands. After great decrease in size of the glands, one of them was removed for examination but no special changes were made out. The fibrosis was no more marked than in the original gland examined. It was suggested by Dr Adam that the increase in size of the glands was largely due to proliferation of the lymphocytes and consequent infiltration of the glands by them. Presumably the x-rays caused these to be absorbed again without any essential change in the gland tissue.

Dr SIMPSON remarked that glands in the posterior triangle of the neck were more important than those in the anterior triangle, as the latter were often enlarged from some septic condition of the mouth. Dr BROWN pointed out that good results could also be obtained by treatment with roentgen.

Mr H. URCOTT showed five cases

1. A man with a calculus in Wharton's duct. Eleven years ago he began to have temporary swelling of the submaxillary gland at meals. Latterly the swelling had become permanent.

2. A woman aged 53 with a large fungating tumour of the cheek. Her upper jaw had been excised thirty-four years ago for sarcoma. A part of this was removed nine years ago, and since then she had had several minor operations on the cheek.

3. A child from whom a finger had been removed. In one aged 52 some small nodules had been removed to that all white bodies could be examined. These were found to be calcified nodules and degenerative in type, apparently not being due to an inflammatory process.

4. A woman aged 33 with metastases of the fibrous tissue of the breast. X-rays showed the whole bone to be very extensively eroded. A similar erosion was present in the condyle of the lower jaw. Four years ago she had total hip trephomy for squamous carcinoma of the cervix. No primary growth could be detected in the breasts or elsewhere.

Reports of Societies.

SPLENIC ENLARGEMENT IN CHILDREN

At a meeting of the Section for the Study of Disease in Children of the Royal Society of Medicine on November 27th, with the President, Mr PHILIP TURNER, in the chair, a discussion on the diagnosis and treatment of splenic enlargement in children was opened by Sir HUMPHRY ROLLESTON, whose paper will be found in full at page 1099.

Dr G. A. SUTHERLAND, continuing the discussion, dealt in some detail with the condition of thrombocytopenic purpura haemorrhagica. This disease was characterized by an enlargement of the spleen and a decrease in the number of platelets in the blood, these two conditions seemed to be related pathologically. Splenectomy appeared to offer the only certain chance of cure. The observed increase in the size of the spleen was not great; it was usually just palpable, although this probably represented two or three times the normal size. There was often some difficulty in diagnosing minor degrees of splenic enlargement, but in children over 2 years of age at any rate a spleen which could be felt was definitely pathological. Two negative findings in this disease were important. There was no change in the blood count except that produced by the anaemia following repeated attacks of haemorrhage, and apart from these haemorrhages and the anaemia they produced there was no disturbance of health. Dr Sutherland emphasized certain points in diagnosis, especially with regard to the decrease in platelets, increase in the bleeding time, and the fact that the clot was non-retractile. He analysed fifty-eight cases in detail by means of tables, and with regard to treatment showed that splenectomy was a real advance. Of these fifty-eight collected cases, fifty patients were in perfect health, and two were improved, while six had died.

Dr L. G. PARSONS dealt with splenic enlargements due to Banti's disease, acholuric jaundice, and lymphadenoma. He pointed out that the existence of the first of these in children was denied by some authorities, and while the full symptom-complex of Banti's disease might be rare, there occurred cases of splenic enlargement of doubtful origin characterized by anaemia and leucopenia with negative Wassermann reaction and normal fragility of the red cells. He described three cases presenting such a syndrome, one of which, however, had shown a leucocytosis. Dealing with acholuric jaundice, Dr Parsons described a method for estimating the fragility of the red cells. In one case of this disease an accessory spleen had been found at operation, and he wondered whether if this were left behind after splenectomy it would hypertrophy and cause recurrence of the disease. In both these groups of cases splenectomy gave excellent results. Syphilis might present a picture almost identical with Banti's disease, and if such a case resisted antisyphilitic treatment splenectomy should be performed. Even if the liver were found to be involved at operation removal of the spleen was not contraindicated, since if cirrhosis was not too far advanced recovery appeared to be a possibility. Lymphadenoma presented some difficulties in diagnosis, but there was usually some glandular enlargement. Pain in the limb might occur and was some help in diagnosis. His experience of the x-ray treatment of this disease was that invariably made the condition worse.

Dr HUGH FULFORD said that he disagreed with much that had been brought forward. He thought that splenic enlargements in early childhood were very important. Under about 4 months the two main causes were syphilis and tuberculosis, and such enlargements were valuable confirmatory evidence if either disease was suspected. From 4 months up to about the third or fourth year enlargement of the spleen was comparatively uncommon. At about 5 or 6 years of age there occurred splenic enlargement of unknown etiology associated with iron anaemia and enlargement of the liver. The whole condition quickly improved without any special treatment and was probably due to some infection. From 6 years onwards splenic enlargement in children was almost always

due to tuberculosis, syphilis, or lymphadenoma. Tuberculosis sometimes occurred in the spleen as the main site in the body, and in such cases splenectomy was justifiable. If none of these three causes were present Dr Thursfield was strongly opposed to calling the condition Banti's disease, which represented a rubbish heap. This diagnosis ought to be reserved for the type of case actually described by Banti. He pointed out that considerable enlargement of the spleen might occur in almost any of the acute specific fevers and this enlargement might persist into convalescence.

Dr CRAMHAM FORBES described some cases of spleno-medullary leukaemia in children.

Dr F. J. POYNTER said that there was much still to be discovered about the spleen. The question of the influence of infection on this organ required further elucidation, and possibly some individuals presented a peculiar blood reaction to infection. He thought that much more investigation of the reticulo-endothelial system was necessary. He pointed out that in some cases of undoubted icteric jaundice in families fragility of the red cells might be normal.

Dr P. PARKES WEBER pointed out that since leucopenia was a common feature of almost any chronic enlargement of the spleen it should not be accepted as evidence of Banti's disease. He agreed that in familial cases of icteric jaundice certain members of the family might have normal fragility of the red cells, and he was strongly opposed to splenectomy in these mild cases.

The PRESIDENT described a case already referred to by Sir Humphry Rolleston where a very large spleen in a boy of 6 with a positive Wassermann reaction resisted treatment over a period of years, and the boy's condition actually made worse by other treatment was cured completely by splenectomy.

Dr L. G. PARSONS, in reply, stressed the fact that the cases of Banti's disease which he had described all showed the microscopic appearances in the spleen associated with this disease.

PUERPERAL SEPSIS

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on December 3rd, with Mr T. G. STEVENS in the chair, papers on the subject of puerperal sepsis were read by Dr H. J. PHILLIPS (Oldham) and Dr L. COLEBROOK (London), the former speaking on the rational treatment of puerperal infection, and the latter on some laboratory investigations in connexion with the subject.

Dr PHILLIPS placed before the Section the results he had obtained at the Monsall Fever Hospital, Manchester, in the treatment of a series of cases of puerperal infection along certain constant lines. In that hospital twenty-two beds were set apart for puerperal cases, and the annual admissions varied from 90 to 120. Though no cases were refused, it still happened that many patients were not brought until their condition was distinctly grave. He had been impressed by the great amount of extra-uterine injury which these women had sustained, and their very septic state when they came to hospital (he was not speaking of toxic peritonium). He had tried to devise a means of assisting the uterus to drain itself by promoting a flow of lymph through it into the cavity. He believed glycerin promised well for the purpose, as it was a powerful tissue dehydrant, and its viscous nature enabled it to remain long in contact with the damaged tissues, moreover, it could be distributed slowly and evenly over the interior of the uterus. A good trial of this had left him pleased with the results. Most of his cases were thus drained once daily, the more severe cases twice a day. The first 100 cases were treated, on the average, seven times each, the course being stopped only when all signs of active inflammation had ceased. The passage of the catheter and injection of the glycerin helped to reveal the presence or absence of pus in the uterus. Pus was present in 50 per cent of his severe cases, in one there was a total of 6 drachms. A profuse purulent vaginal discharge had often been taken by the medical man as an indication that the uterus was draining well, when in fact none of the discharge was

coming from the uterus, the source being high up in the vagina. He gave a comparison of two series of cases which had received. The first was a table of 87 cases which were treated by lymph drainage of the uterus, with iodine added to promote uterine contraction, and the second a series of 110 cases treated immediately before instituting the glycerin treatment. The cases before the new procedure had been treated along three main lines. The milder ones had vaginal douching, Fowler's solution, quinine, and so forth, and the more severe had been treated with antistreptococcal serum or curetting. Of the 110 cases, 88 were treated expectantly, 17 with antistreptococcal serum, and 5 by curetting. Of these 29 per cent developed complications after coming for treatment, 11 of the patients producing pus so as to require operation. Of the 87 cases treated by lymph drainage only 13.7 per cent had complications, or half the proportion in the other series, while only one patient of the series developed pus. He showed on the screen detailed tables of cases. The percentage mortality in the first 100 cases treated by the new method was 13, the lowest figure in the institution for many years. All the 13 cases who died in this series succumbed to a condition which had become definitely established before the patient's admission to hospital. The stay in hospital also had now been much reduced. In former days patients who recovered stayed in the hospital an average of 38 days, now the period was 26.2 days. Concerning the acute blood infections, Dr PHILLIPS had, on the suggestion of Dr Colebrook, adopted two lines of treatment: first, the intravenous injection of arsenical drugs as a bactericidal agent, secondly, the transfusion of immunized blood to aid the patient's own defensive mechanism. The arsenical preparation preferred was novarsenobillon, and the results were best after giving large doses. The improvement following the use of this preparation was remarkable, in some cases dramatic. The results of the transfusions were not so striking.

Dr L. COLEBROOK, in the course of his paper, set out some results of laboratory investigations in connexion with puerperal sepsis. It was necessary, he said, to ascertain what was the chief microbial agent in the production of puerperal sepsis, and his own view was that it was the haemolytic streptococcus which caused 90 per cent of the trouble in septicæmic cases and perhaps of localized infections. As to the manner in which the streptococcus got into the genital tract generally, it was taught that the organism was not normally in the vagina, but might it not be that in these conditions the non-haemolytic form of the streptococcus was transformed? The non-haemolytic were more easily killed by leucocytes than were the haemolytic. Was there any evidence that the woman's resistance to the streptococcus was lowered by the conditions obtaining in labour and the puerperium? Experiments had shown that there was no general tendency in these states for the killing power of the blood to be decreased, and if a few streptococci got through, the woman's blood being normal, they had little chance of surviving in the capillaries. In septicaemia the patient's killing power was enormously reduced, in some cases to only 40 per cent of the normal. In severe streptococcal septicaemia the leucocytes were not the normal ones, hence the defective bactericidal power. The significance of the fact of streptococci found circulating in the blood stream was largely a question of numbers, and he advocated that the report of the pathologist in these matters should include the numbers seen per cubic centimetre. He had never seen a woman recover whose blood had more than 100 streptococci per c.c.m. The war experiences had taught the lesson that wounds infected with haemolytic streptococci and containing damaged tissue could not safely be left to themselves, as Sir Almroth Wright had abundantly shown. The worst cases of puerperal fever were those in which the lochia were suppressed and those in which the use of instruments had resulted in bruising. The great point about the treatment of these conditions was to cause an outward flow, and this was well secured by the use of glycerin, which Dr PHILLIPS had just described, perhaps its value was due to its viscosity. He did not believe a real case had been made out for the use of antistreptococcal serum, when mixed with the blood no additional killing power could be demonstrated in it as a

handicapped, a kidney which had been obstructed for four weeks would assume complete function. These experiments showed that the medulla was compressed by pelvic distension and the arteriae rectae showed preshortening. When the pressure was directed to the cortex there was congestion, followed by atrophy, especially in the sub-cortical glomeruli. Lastly, the peripical glomeruli atrophied.

SIR DAVID WALLACE thanked the officials of the society for their help, and referred to the change of meeting place. He drew attention to the number of papers relating to tuberculosis read during his term of office, papers dealing with the subject from the clinical, bacteriological, veterinary, and research standpoints. In January, 1913, Mr John Fraser had read a paper on bone tuberculosis, and a committee of the society was formed to inquire into the relation of the milk supply and the prevalence of tuberculosis in Edinburgh. Again, during the session 1924-25, the society had returned to the subject, approaching it from a different angle but with the same object in view. Among many interesting subjects discussed was erythroedema, the use of the bronchoscope in chest diseases, as described by Dr Ewart Martin. The many interesting discussions, communications, and demonstrations merited a large attendance of members. The special discussions had been on congenital or inherited syphilis, opened by Mr David Lees, on viscerotoposis, by Dr Robert Hutchison, on the milk supply of the country and its bearings on health, by Professor Sir Robert Philip, on the pituitary gland, by Professor Sir L. Sharpey-Schafer.

DIATHERMY IN CARDIO-VASCULAR DISEASE

At a meeting of the Liverpool Medical Institution on November 26th Dr J HAY and Dr PHOEBE LACE read a short paper dealing with the uses of diathermy in the treatment of patients suffering from cardio vascular disease, more particularly in patients with major and minor angina, in cases of high blood pressure with various manifestations of distress, and in one case of intermittent claudication. Some of the patients had been kept under observation for many years, and the effects of the diathermy had been noted for the last two years. Weekly records had been kept of the variations in blood pressure, both systolic and diastolic, in the heart rate, and in the clinical findings, showing the response to treatment. In most instances there was definite benefit, and in some cases dramatic improvement. Not only were the pressures reduced as the immediate result of treatment, but when the course of treatment terminated the improvement was maintained. In nearly every case, whatever the variations in blood pressure, there was marked subjective improvement. The response to treatment was much more satisfactory in the males than in the females. In considering these results there appeared to be no doubt as to the benefit derived from this line of treatment.

Grafts

Mr R E KELLY read a paper on grafts and grafting. After a brief historical survey, he considered the various methods of skin grafting. He said that the essential features in a successful Thierch graft on a granulating area were as follows:

1 The area must have a flat instead of a heaped up edge. This could be obtained by Beck's method of protecting the growing epithelial margin by strips of half inch zinc oxide eye-trapping for a few days. By this means the exuberant granulations were flattened out and the marginal cranny of pus obliterated. Further it saved the delicate new epithelial edge from being pulled off with the dressing. The last dressing should consist of 50 per cent alcohol.

2 The granulating area must neither bleed nor seep. It should have no other drainage nor drain.

3 The operation should be performed with absolute dryness. As one showed there were disadvantages in moistening the area with saline, glycerin or antiseptic. No dressing was needed. Around the area a nest of gauze was placed and cut up of this but not touching the graft a piece of celluloid was pressed down with taping.

In immediate grafting Mr Kelly mentioned the value of a "cut" or distal wax case, over the graft so as to apply even pressure and prevent the exudation of serum

between the bed and the graft. He then referred to the many grafts of Lescr, Gillies, and Pickarill, and showed examples of eyelid grafting for ectropion and whole skin grafts for the deformity following lupus of the face. Photographs of the tubed or jug-handle graft were shown, illustrating the restoration of a lower lip lost by cancer of the oris in infancy. He described Gillies's work on the tibia-fasciae femoris and its multifarious uses as a grafting material. He showed cases in which he had used it for uniting a fractured patella, for repairing an extensive post-operative hernia, and even for repairing an inch gap in the extensor secundus internodii pollicis tendon. This had been one of Mr Kelly's most successful fascial grafts. The result after a year was complete and strong movement of the terminal phalanx in absolute contradistinction to a similar operation on the flexor tendons of the palm, where, despite primary union, the palmar operations had failed. There appeared to be too much fibrosis, and the grafts had stuck to the palmar fascia. Cartilage grafts for nasal deformities were next considered. They were extremely useful in accidental depressions, but were apt to be disappointing for cases of congenital syphilis. Finally, Mr Kelly described his method of wedge-shaped bone graft. He had used this for the fibula to prevent the slipping of the peroneal tendons and in the tibia to bridge a gap of an inch or so. The paper was illustrated by lantern slide, and there was a preliminary exhibition of the patient.

INSULIN TREATMENT

At a meeting of the Chelsea Clinical Society held in the Board Room of St George's Hospital on November 17th, Dr SERVORN PRIOR, the President, in the chair, Dr E P POULTON introduced the subject of insulin treatment.

Dr Poulton said that his plan of giving insulin was to increase it up to such a dose, twice in the day (three times if necessary), that the urine remained permanently sugar-free, while the patient did not get any signs of an insulin reaction, in the ordinary circumstances of his life, but he thought it important that the patient should experience a reaction during the preliminary test period, so that he would know what it felt like. Mild cases of diabetes might be dieted, if after a period the blood sugar became approximately normal, and the patient lost all his symptoms, and in particular his sense of fatigue, then insulin was not required. Dr Poulton showed results of Dr Payne's researches at Guy's Hospital—namely, that toast produced a smaller rise in the blood sugar of a diabetic patient than a similar quantity of bread, and that artichokes, which contained insulin, were tolerated better than almost any other vegetable. In rather more than half his cases treated on these lines it was necessary to reduce the dose of insulin after the treatment had been in progress for two years.

Dr GEORGE GRAHAM said that while insulin would have to be given continuously to all cases of severe diabetes, and, of course, to all cases which had been restored from coma, this was not so in the mild cases. If the dose of insulin was small it was always possible to give up insulin provided the carbohydrate was reduced at the same time. Most patients preferred to take insulin, partly to keep their extra carbohydrate, and partly because they felt so well. The chief danger for the diabetic patient lay in the occurrence of other diseases, both major and minor. The major infections always put the patient in danger of coma, and of nine cases of coma no fewer than eight had a severe secondary infection of some sort. The minor infections might lower the sugar tolerance considerably, and it was not possible to measure this in terms of insulin. A very mild attack of German measles had increased the insulin requirements of a child of 8 by twelve units. It seemed advisable to increase the dose of insulin by two or four units, as soon as the infection started, irrespective of whether sugar was present in the urine or not. In severe infections the dose of insulin might have to be increased up to 100 or 200 units. A scheme of gauging the safe dose of insulin was described. He had not known any case of renal glycosuria which had developed into true diabetes, but he pointed out that such a person was as

likely, but no more likely, to suffer from true diabetes as anyone else

Dr P J CAMBRIDGE said insulin was no longer looked upon as a cure for diabetes. It was only necessary to give it, on the average, in about one-third of the cases, these were mainly children or adults suffering from complications, such as acidosis or gangrene. In cases of true pancreatic diabetes insulin acted as a substitute for the missing internal secretions. In other forms it was a means by which physiological rest could be obtained for the exhausted gland. In this connexion it was necessary to bear in mind the relation found to exist between the internal secretion of the pancreas, adrenals, parathyroid, thyroid, and pituitary. The last named, although not taking part in carbohydrate metabolism directly, was capable of indirectly influencing the process by the property it possessed of combining with the insulin—a property which accounted for some of the puzzling effects of insulin constantly met with.

Dr F G CROOKSHANK, who said that he spoke from the standpoint of the general physician, which approached that of the general practitioner, rather than that of the specialist in diabetes, wished to emphasize that apart from its great and unquestioned value in early life, and in coma and gangrene, the role of insulin therapy seemed to be increasingly the paradoxical one of trying to enable patients to do without it. Before the introduction of insulin therapy it was difficult to interest either practitioner or patient in the various "fasting" and graduated dietetic methods. Now the practitioner who desired admission to the hospital for a case to "see what insulin can do for it" was at once interested when he found how much could sometimes be done without insulin. Too early recourse to insulin occasionally prevented a patient receiving the benefit, sometimes remarkable, that might in early cases attend the removal of oral sepsis. The remarkable change brought about sometimes in glycosuria by removal of oral sepsis gave point to a suggestion of the late Dr Vivian Poore, that possibly the part played by the parotid secretion in carbohydrate metabolism and in diabetes was undervalued. Oral sepsis affected the parotid secretion, by ascending infection and occlusion of Stenson's duct, the point was perhaps worthy of investigation.

Dr HILDBRED CARLILL related a case of diabetes in a young child in whom a portion of pancreas had been grafted. The case so far was very encouraging.

PATENCY OF THE TUBES IN STERILITY

At a meeting of the Brighton and Sussex Medical-Chirurgical Society on December 3rd with Mr H J WALKER, the President, in the chair, Mr HAROLD F SEYMOUR read a paper on some recent methods of investigating the patency of the Fallopian tubes in sterility. He said it was only within the last two or three years that a technique had been worked out which showed satisfactorily whether the tubes were blocked or not. After mentioning the various contraindications he described certain methods. Rubin of New York injected carbon dioxide through a uterine cannula, the pressure of the gas being indicated by a manometer. The apparatus was fully described and shown. The advantage of carbon dioxide over air was that the former was absorbed so much more rapidly, and consequently it was more comfortable for the patient. Mr Seymour thought the water displacement meter used by Rubin was excellent, since it allowed the gas to flow gently. Victor Bonney's simple method of using air was referred to, and Forsdike's method of injecting air through a hollow uterine dilator was described. By any of these means it was easy to determine if there was a free passage through the tubes, and the test had now become a recognized gynaecological procedure. That insufflation of the tubes had a therapeutic effect as well as a diagnostic side was illustrated by one of Mr Seymour's cases. When the tubes were shown to be blocked the next procedure was to localize the block in collaboration with the radiologist. The methods were as follows: (1) The process originated by Forsdike, where lipiodol was used as the opaque substance. (2) The other method involved the introduction of barium sulphate emulsion into the body of the uterus, it was recommended by some gynaecologists. Mr Seymour preferred Rubin's apparatus for diagnosing the block, and Forsdike's lipiodol method for locating the position of the block. Mr Seymour then read a short paper on the possibilities of endoscopy of the uterus, and described his own hysteroscope.

Reviews.

HIP DISEASE

In his small book entitled *The Diagnosis and Treatment of Tuberculosis of the Hip* Mr GIRDLESTONE has placed before the public the fruits of his experience at the Wingfield Orthopaedic Hospital. Its subject, as he says, is purely clinical. It follows cases from the preliminary consultation and diagnosis through the three stages of treatment in an open-air hospital. Finally, "end-results" are classified and operations described.

In a small space every aspect of the disease is discussed and the differential diagnosis between it and transient synovitis, coxa vara, arthritis (chronic and septic), and syphilis is set forth. With all the means at our disposal and all the experience gained at such a hospital as the Wingfield, diagnosis will in some cases remain doubtful and must be treated as though positively tuberculous. There is, as Mr Girdlestone says, great need of a test for tuberculosis as trustworthy as the Wassermann or Sigma test is for syphilis.

For treatment in the early stages he relies upon the Jones abduction frame. It is scarcely necessary to state that throughout the treatment heliotherapy in an open-air hospital is assumed. When, as most often happens, ankylosis is the end-result to be expected, the question of the best functional position arises. Some degree of abduction and flexion is recommended, varying according to the age of the patient. All authorities are now agreed that excision of the joint has no place in the treatment of children, but in adults it may often be advisable as a stage in the production of arthrodesis.

The Thomas hip splint is only recommended for the third and last stage of the disease, when ankylosis is occurring or being consolidated. In cases of bad sepsis with sinuses and hectic fever Mr Girdlestone has recourse to drastic measures to procure radical drainage. Through transverse incisions he excises parts of the pectineus and long and short adductors on the inner side and of the gluteus medius and minimus upon the outer, suturing the skin down over the cut edges.

The various operations for the corrections of deformity after active disease has ceased and ankylosis is firm are described, including that devised by the author for pseudoarthrosis, in which the transplanted trochanter takes the place of the destroyed head of the femur. There is a useful note on the mechanics of the hip-joint.

The book is likely to be of value to anyone who has charge of a case of hip disease and would treat it in the most satisfactory manner. The advice is given in clear language and the directions are explicit. The clear illustrations enhance its value.

LECTURES ON DYSPEPSIA

Dr ROBERT HUTCHISON, in his *Lectures on Dyspepsia*, does not confine himself to disorders of the stomach, he includes also chronic constipation, chronic diarrhoea, and mucomembranous colitis, and ends up gracefully and with humour on the "chronic abdomen." Though in the introduction he expressly states that the book is intended solely to help the practitioner in a common but difficult department of medicine, we cannot help thinking that it may appeal to a wider circle.

The lectures are the fruit of years of experience, they are filled with helpful and suggestive advice, and if the author has not adopted the language of aphorism it is probably because he knows too well the dangers of this mode of expression. One of his main endeavours is to render assistance in the diagnosis between organic and functional disease, pointing out that most organic dyspepsias require surgical treatment, and most functional dyspepsias are of nervous origin. But we must not anticipate its contents, we will

The Diagnosis and Treatment of Tuberculosis of the Hip By G R Girdlestone. B.M.O. on F.R.C.S. Oxford Medical Publication. London Humphrey Milford Oxford University Press 1925 (Demy 8vo pp 2+34 60 figures 8s 6d net).

leave the joy of consuming them to the practitioner, trusting that his patients will benefit to the same extent that he himself is sure to do

IMMUNOLOGICAL WORK OF THE GLASGOW SCHOOL

Immunochemical Studies,³ edited by Dr. CARL BROWNING, is a book dedicated to Professor Robert Muir on the occasion of the completion of the twenty-fifth year of his work at the pathological department of the University and Western Infirmary, Glasgow. Six of his former pupils, who now occupy responsible pathological posts, have contributed to it—namely, Dr. Browning of Glasgow, Dr. Mackie of Edinburgh, Dr. Wilson of Birmingham, and Drs. Kosaki, Taniuchi, and Yoshinara of Japan. Nearly all the material of the book consists of reprints of articles contributed to scientific journals, principally the *Journal of Pathology and Bacteriology*, these have been arranged in order, which gives continuity to the story, and some alterations made where necessary. Dr. Browning has written an introductory chapter on antibody action in general, in order to give readers not personally engaged in immunological investigations an indication of the relation between what one may call the Glasgow school and other schools of thought.

The detailed table of contents at the beginning of the book gives a good plan of the ground which is covered and is designed to serve instead of an index. Because of its general design the book is naturally not a complete exposition of current ideas about immunity, but it is a convenient collection of the views of a number of workers who have given special study to immunity problems.

PITFALLS OF SURGERY

Mr. HAROLD BURROWS's book, of which the first edition fell unfortunately into the hands of lay newspaper writers has now appeared in a second edition under the less provocative title *Pitfalls of Surgery*.⁴ As Mr. Burrows says, textbooks and teachers have been so much concerned with constructive information that relatively little has been said about the difficulties and dangers of surgery. Therefore his book is filled with a collection of mischances garnered from experience, and flavoured with some of the author's private convictions. The collection is very complete, and its gathering must have cost Mr. Burrows much time and labour. He has compiled it from his own mistakes, from the recorded errors of other surgeons, and from disastrous incidents which have occurred in general practice. Withal the book is written in a spirit of charity, as when appreciation is shown of the difficulties of the general practitioner in cases of acute abdominal disease, by the remark that "his trial has been hard, while criticism is very easy." Moreover, if the general practitioner is often guilty of unnecessary delay, Mr. Burrows adds that the surgeon frequently fails through excessive haste. Thus a list is given of general disorders in which the symptoms of vomiting and abdominal pain have been the insecure foundations on which a diagnosis of appendicitis has been built.

Mr. Burrows emphasizes the value of an accurate history, the absolute necessity for a thorough and not merely a local examination of the patient, and the fallacy of relying upon individual symptoms. He divides the main tributary streams of error into ignorance, carelessness, misjudgement, and defective technique. He deplores the neglect of post-graduation study and the small need that exists, so far as success in practice goes, for keeping abreast of modern progress. He deals gently with the surgeon who overrates his own capacity, but looks on the occasional operator as dangerous. It is possible to disagree with Mr. Burrows, as when he says that a new source of diagnostic error lies in "a to which he give the name 'the fallacy of collective responsibility' in the group clinics. The plan is said to be 'to rail because a medicine is an art and no work of art can reach a high level when it is the product of a group

of individuals each of whom has a controlling interest. It is quite possible that the group clinic may be most useful, where the clinic is perhaps liable to fail is in not recognizing the value of the balanced judgement of the good general practitioner who ought to be attending, and who knows, the patient.

Mr. Burrows's book is fascinating if only for its new and delicate method of handling a subject which must have caused remorse to many surgeons and practitioners. And if in our earlier review we felt called upon to criticize adversely the title and some of the contents of the book, we are glad to recognize that in both matters Mr. Burrows has shown appreciation of the criticism.

HEREDITY AND MENTAL DISEASE

PROFESSOR ABRAHAM MYERSON has written a suggestive and interesting volume on *The Inheritance of Mental Diseases*.⁵ Its special value may perhaps be said to depend upon its insistence on the view that the hereditary transmission of mental disease is essentially a medical problem to be attacked in the main by clinical experimental methods such as have been found effective in the study of other diseases. The author takes the view that when we have data sufficiently accurate and representing the facts of a more intensive study of individual cases it will be possible to call on statisticians and biometrists to help formulate laws, but that the time for this has not yet arrived. In approaching the problem of mental disease it is encouraging to remind ourselves that as our knowledge of certain diseases has increased, heredity, in the sense used by biologists, is tending to recede more and more into the background as a causal factor. The author illustrates his point by observing that down to the time of the discovery of the tubercle bacillus by Koch the main factor in the causation of tuberculosis was held to be heredity. Just as to-day we speak of the psychopathic inheritance, so our predecessors of past medical generations spoke of the "scrofulous type," which was made to include everything from slenderness to flunting, including rickets (which we now know to be dietetic in origin), catarrhal affections of the throat and nose (usually due to tonsillitis and adenoid hypertrophy), tetany (a defect in calcium metabolism), and so on. With the discovery of the infecting organism as a cause of tuberculosis, heredity, Professor Myerson says, received a knock out blow, we now know that the human being easily acquires this disease under bad conditions of living, that good conditions of living ward it off, that it is treatable by diet, rest, and hygiene, that the environment causes it, in short, and that by control of the environment the disease can be controlled in a remarkably successful way, as is now being done.

The polymorphic theory of the heredity of mental diseases, by which it is held that there is a unitary something in the psychopathic inheritance which makes itself manifest under many forms, is submitted to vigorous criticism. In the excessive development of this theory all manner of mental diseases, including the organic diseases, all psychoses, epilepsies, feeble-mindedness, crime, alcoholism, eccentricity, and even headache in an ancestor, are given hereditary value in relation to the mental disease of his descendant. It is obvious that statistics based on the assumption that conditions so diverse and due to such a variety of causes have a unitary quality which can be transmitted must lay themselves open to serious criticism. The author himself regards Forel's theory of blastophoria (germ-plasm injury) as the most useful working hypothesis for the study of family mental disease, and he brings forward many arguments in support of the view that transmissible mental diseases may not be true hereditary characters, in the sense that stature and blue eyes are hereditary characters, but that they represent diseases, caused by unknown agents having effects which may persist over two or more generations and from which a stock may die or recover. He feels that it is more logical to search the environment for the causes of family mental disease than

to fall back on "pure heredity." The environment offers a more hopeful prognosis, for it will be easier to alter the environment than to induce the genius, the queer, the nervous, the criminal, the alcoholic, the migrainous, and the gouty to refrain from sexual life and parenthood. If we too readily assume heredity of an inevitable kind as a cause, the result is to cause paralysis of investigation, for any fundamentally fatalistic doctrine inhibits research, it, on the other hand, we say that the environment, in some of its forms, as toxins, infection, and lowerer of vitality, acts in a blastophonic way, we are stirred to research and results will follow.

The book includes an account of the various clinical groups of mental disease, the marriage rate of these groups, the relation of sex to family mental disease, the way diseases go from generation to generation, and the path they take in the same generation. The volume may be recommended as a stimulating and helpful contribution to psychiatry.

SAVILL'S "CLINICAL MEDICINE"

THE high reputation SAVILL'S *System of Clinical Medicine* has earned throughout its successive appearances is fully maintained in its latest edition, the seventh.* Dr Agnes Savill, who has so ably edited the four editions issued since her husband's death, has been constrained to enlarge the present by some fifty pages at the cost of very considerable rewriting. The whole work has been thoroughly revised and brought up to date, and in this task Dr Savill has had the co-operation of a number of experts. Dr J Strickland Goodall has revised and in many parts rewritten the chapter on diseases of the heart. Revision of the chapter on diseases of the nervous system has been again carried out by Dr Harry Campbell. The chapter on diseases of the stomach has been revised by Dr S W Patterson, that on diseases of the eye by Dr Angus MacGillivray, and that dealing with fevers by Dr J D Rolleston. Others to whose assistance the editor expresses her indebtedness are Dr Robert Cole, Sir James Dundas-Graham, Mr Philip Fraulini, Colonel W S Byam, Professor Louise McIlroy, Dr Skene Keith, Dr Leonard Williams, Dr Langdon Brown, Dr Gordon Ward, Dr Scarpure, and Dr Reginald Hilton.

This process of revision has in no wise affected the plan of the work, which has made so successful an appeal because of its eminently practical character. It deals with the various diseases from the standpoint of symptomatology, the principle being first to describe the symptoms and then to trace these back to their causes. The introductory chapter in which the author explained his method and his reasons for adopting it, is reproduced unaltered in this as in every previous edition. We can again cordially recommend Dr Savill's book to students and practitioners.

NOTES ON BOOKS

AT the 1925 Congress of the Health Association of Australia the presidential address was delivered by Sir JAMES BARRETT, M D, who took as his subject "The birth and growth of the conception of the prevention of disease." The address has now been printed in a pamphlet. At the outset Sir James Barrett explained how the Health Association had originated at the eleventh session of the Australasian Medical Congress at Brisbane in 1920. It had been established by the initiative of several American public health officers who were employed in Australia on the hookworm campaign. At first it was modelled on the lines of an American Health Association, but later had become considerably modified in its constitution. He traced the gradual growth of the conception of preventive medicine from ancient times up to the present day. He showed how the peoples of the Middle Ages were faced with the urgent problems of the control of epidemic disease. The development of the practice of isolation in medieval times foreshadowed the modern public health movement. Coming to later days, Sir James Barrett referred to the extinction of scurvy in the navy made possible by the work of two naval surgeons, Dr James Lind and Sir Gilbert Blane, and to the prevention of small pox by reason of Jenner's epoch making discovery in 1798. Later the work of Pasteur, of Lister, and of Koch was to change the entire outlook on the possibility of the prevention of disease. In conclusion the president laid particular stress on the need for public education in health in all sections and conditions of society.

* *System of Clinical Medicine*. By Thomas Dixon Savill M D Lond. Seventh edition. London: Edward Arnold and Co. 1925. (Med 8vo, pp. xxviii + 1094, 176 figures, 4 plates, 28s net.)
H. Bourne, Brown Prior and Co.

We have received the thirteenth edition of *The American Illustrated Medical Dictionary* by Dr NEWMAN DORLAND.* It is stated that about 2,500 new words have been introduced, and the work has been carefully revised throughout. An unusual feature of this dictionary is the amount of space occupied by special tables. Thus, no fewer than thirteen pages are devoted to stains and staining methods, and twenty eight pages to different kinds of tests, a tabulated list of treatments occupies three pages. Other tables are provided for the nerves, including their function, origin, distribution, and branches, and the muscles, their origin, insertion, nerve supply, and action. Numerous illustrations—many of them coloured—add to the value of this dictionary as a work of reference. Though it makes no claim to be an encyclopaedia, "Dorland" has gone some way in that direction, while retaining a convenient size and commendable clearness of type. It is a matter for some regret that the British profession should nowadays be dependent on the United States for its medical dictionaries, if only because spelling and usage vary in the two countries, but we must, none the less, be grateful for the accuracy and comprehensiveness of the work undertaken by such painstaking editors and compilers as Dr Dorland.

Among the artists drawn upon for pictures to illustrate the *Medical Art Calendar* for 1926 are Rembrandt, Jan Steen, David Teniers, and Gerard Don, but it contains reproductions of many less known artists, nearly all Dutch, and also some engravings. Most of the pictures are character groups of doctors visiting or operating on patients, but there are a certain number of portraits. The first picture is by Rembrandt depicting the Apocryphal story of an operation being performed by Tobias under the direction of the angel. This year there are only a few alchemists, but there are several dentists, both regular and quack. There is a delightful character picture by Cornelis Troost (1697-1750), who has been called the Dutch Hogarth, it shows an elaborately furnished lying-in chamber, with the nurse, grandmother, and most of the family assembled. The present calendar is quite up to the standard of its predecessors, and will be an interesting ornament for a corner of the consulting or waiting room. The calendar is published by Mr J Philip Kruseman at the Hague, and will be supplied by him in this country post free on receipt of 6s.

* *The American Illustrated Medical Dictionary*. By W A Newman Dorland A M M D F A C S. Thirteenth edition revised and enlarged. Philadelphia and London: W B Saunders Company, 1925. (Med 8vo, pp. 1344 illustrated, 35 net with thumb index 37 6d net.)

PREPARATIONS AND APPLIANCES

A Laxative Paraffin Mixture

ACAROL Brand Compound is a mixture of mineral oil and agar agar with 3/4 gram of phenolphthalein to the teaspoonful. Mixtures of this type which produce a mild laxative action slightly greater than that of liquid paraffin alone, are deservedly popular in the treatment of chronic constipation. We are informed by the agents, Messrs Newbery (31 Banner Street, London, E.C.1), that it is not proposed to extend advertising in any form to the general public.

The I W C Feeding Bottle

An expert subcommittee of the Association of Infant Welfare Centres (which is a constituent section of the National League for Health, Maternity and Child Welfare) has recently brought out an infant's feeding bottle, claimed to be the best and the cheapest yet produced. We have examined a sample and have formed the opinion that feeding an infant by means of this bottle approximates as nearly as is possible to the natural method. It has a teat moulded in a substance resembling thin India rubber in appearance for which it is claimed that it will not get out of shape nor split nor perish in any climate. In shape it is modelled on a well developed human nipple and is readily everted for cleaning. At the top of the teat there is one hole in the centre of a small thickened area which is intended to supply a greater resistance to the infant's gums. At the base of the teat is a thickened collar with a small rim which fits below the rim on the neck of the bottle. This contrivance effectually prevents the infant from pulling off the teat. Just above this collar is a new feature—a small valve—which allows air to enter as the milk is sucked out, and does away with the necessity of a valve in the bottle.

The bottle is made of strong white glass which will stand heat. It is flat bottomed so that it stands quite steadily, but the inner corners are rounded. The shoulders slope very gradually from the wide mouth to the greatest width of the bottle so that the whole of the interior is easily accessible for cleaning. The outer markings are completely round the bottle and the half-ounce marks only half way round. Both bottle and teat are marked I W C. The complete feeder (bottle and teat) can be obtained from the National League (117 Piccadilly) price 9d, one dozen for 8s 3d, one gross for £4 5 (packing and carriage extra). This feeder has, it is stated, been tested by experts on well and ailing babies over a considerable period, and the reports have been quite satisfactory. The National League is to be congratulated on adequately fulfilling a want.

MEDICAL INSURANCE AGENCY

A MEETING of the Medical Insurance Agency was held at the House of the British Medical Association on December 2nd, when the chairman, Sir HUMPHRY ROLLESTON, Bart, presided. Mr Bishop Harman and Dr R. A. Bolam were elected members of the Committee of Management. The Chairman presented two reports, one for the year 1924 and the other for the nine months ending September, 1925.

REPORT AND FINANCIAL STATEMENT FOR 1924

The report for 1924 stated that there had been a steady increase in practically every branch of insurance negotiated by the Agency on behalf of members of the profession, and it was satisfactory to note that an ever-increasing number of medical men were taking advantage of the various services which the Agency can now offer. The report continued as follows:

Income

During the year under review the Agency maintained the very high standard of former years in the volume of new life business transacted, and for the fifth year in succession placed on behalf of members life and endowment assurances, etc., totalling over £100,000 in sums assured. In addition, annuity bonds, showing a very good return, were purchased to the extent of £6,031 8s. It will be realized that to keep up the standard previously attained, not only has the Agency to secure life proposals equalling the amount in former years, but to increase it very considerably, in order to meet increasing expenditure.

In motor car insurance there was a steady increase principally due to the special policy which the Agency was able to secure on behalf of medical men, and which is only obtainable through its medium. The full effects of this special motor insurance would not be felt for some time, but the policies were being largely taken up. The Agency had secured very good service in the matter of claims settlements, etc., at the same time being able to keep the premiums on a moderate scale.

Workmen's compensation insurances showed a small decrease but this was looked for from year to year, as it was seldom that separate policies were taken to cover servants, etc., the insurances being mostly combined with other household risks. This was reflected in the increase shown for combined household, fire, and burglary insurances.

In accident and sickness there was an increase but this was hardly likely to be a large increase as most of the sickness and accident business was sent to the Medical Sickness, Annuity and Life Assurance Society, Ltd., which paid no commission on introductions.

Owing to the increased premium income the Agency had been able to keep a somewhat larger average amount on deposit than in the previous year. The total income from all sources amounted to £7,192 12s 9d, which was an increase of £1,784 12s 9d over the previous year, and reflected the steady work of the Agency.

Expenditure

Substantial increases in rebates in all branches except employers' liability had been paid, this was a direct benefit to the medical men and women insuring through the Agency.

In employers' liability (accident) business there was a small decrease, accounted for principally by the fact that under a new system the commissions payable in respect of employers' liability insurances had been reduced to 10 per cent and 5 per cent, as against 15 per cent and 10 per cent previously.

Office expenses and clerical staff salaries had increased, but not to any large extent.

After allowance had been made for all increases in expenditure, the surplus for the year carried to the medical benevolent account was some £251 more than in the previous year, and the amount unallotted was £2,419 11s 2d.

The report of the chairman and the balance sheet and accounts for the year 1924 duly audited by Messrs Price Waterhouse and Co., were approved and entered on the minutes.

Interim Report for 1925

The interim report, covering the period January 1st to September 30th, 1925, presented by the secretary, Mr Ferris-Scott, showed that substantial progress had been made. It was as follows:

Life Assurance—It will be remembered that the outstanding features of the Agency's work since the year 1920 has been the securing of life insurances to total £100,000 or over in each year. This rate has been maintained and all records have been broken during 1925 when the Agency introduced on behalf of members of the medical profession over £106,000 during the first half year, and increased this figure to £134,400 for the nine months. These insurances had been spread over a number of first-class companies and the greatest care was taken in the selection of policies. There was reason to believe that investments made

through the Agency on behalf of the assured will show good results. During the nine months under review the actual proposals received numbered 155, covering sums assured of £148,174. Of these, 138 policies, amounting to £134,394, were actually completed. The other seventeen proposals were for sums assured of £13,780, which were either declined by the companies concerned or not taken up by the proposers for various reasons. This low percentage of non-completions (under 10 per cent) compared favourably with the general records of all the leading companies.

In order to bring this information up to the date of the meeting it was reported that proposals had been received totalling £162,785 since the beginning of 1925. The Agency had justifiable cause for pride in the fact that since its inception in 1907 it has placed on behalf of members of the medical profession life, endowment, and other assurances totalling over £1,000,000 (one million pounds).

Many members of the medical profession upon retirement invest in annuity bonds, and the Agency, which is frequently consulted in regard to this class of business, has been able to secure bonds giving good returns to the annuitants. This purchase of annuities requires very careful watching.

Motor Car Insurance continued to engage the serious attention of the Agency, but there seemed to be no prospect for the time being of lower rates. Motor car insurance premiums were admittedly heavy and were likely to remain so in view of the claims experience, the high cost of repairs, and the heavy payments that have to be made to third parties involved in accidents. The doctors' special policy, obtainable only through the Medical Insurance Agency and written by one of the leading groups of underwriters at Lloyd's, did, however, give adequate cover at a moderate cost, and the service received was excellent. During the period under review every claim had been settled to the satisfaction of the parties concerned. Since September, 1924, 333 claims had been settled by the underwriters, the amounts ranging from £83 0 4d in one claim, £315 7s 1d in another, to sums of £1. There had been two fatal accident claims in the last two months. No further proof would seem to be needed of the necessity for medical men to be properly and safely insured. Starting in January last the doctors' special policy had been brought to the notice of every medical man insured through the Agency for motor car insurances with the tariff and other companies. The Agency was fully aware that if these contracts were taken up in any large numbers the premium income and consequently the commission earned would be seriously affected, as the premiums for the special policy are on the whole about 10 per cent lower than those ruling elsewhere. Renewals of policies were, however, maintained at a high percentage, and some 200 new policies have been placed. With new policies being taken up at the rate of one a day, progress in motor car insurance, despite the reduced premiums, could be reported.

Household, Fire and Burglary, Accident, Sickness, and Workmen's Compensation Insurance had all continued to increase steadily.

During the nine months the premiums debited to the Agency totalled £44,790, as against £41,072.

Technical Advice on Purchase, etc., of Motor Cars—It is now possible to see the result of two full years' working of the scheme existing between the consulting engineers Messrs Mann, Egerton and Co., and the Agency. Verbal as well as written evidence had been received that the engineers had spared no effort to give satisfaction to members of the medical profession and to render the service offered of very real use and value.

Although the business introduced through the Agency is now reaching large proportions, it must be remembered that it is only by the purchase of motor cars, spare parts, etc., by members through this firm that the engineers can be rewarded for the helpful advice and ungrudging assistance they give.

Grants to Medical Charities—Out of the balance standing to the credit of the Medical Benevolent Account, the following grants were made by the Committee of Management:

	£	s	d
Royal Medical Benevolent Fund	525	0	0
Royal Medical Benevolent Fund Guild	525	0	0
Uxbridge College Benevolent Fund	525	0	0
Educational Grants (Girls) Subcommittee	210	0	0
British Medical Association Charities Fund	157	10	0
Royal Medical Benevolent Fund Christmas Appeal	52	10	0
Royal Home for Incurables, Putney	52	10	0
Birmingham Medical Benevolent Society	26	5	0
Lancet, Editor's Discretionary Fund	26	5	0
	£2,100	0	0

As a result of this distribution the total sum subscribed to medical charities by the Medical Insurance Agency since 1910 has exceeded £14,350.

Some time ago the Committee of Management established a Girls' Education Fund, which has been allowed to accumulate. A subcommittee was appointed to report upon the suggestions for the use of the fund, and it was resolved to elect one of the members of the committee of the Royal Medical Benevolent Fund Guild to be a member of the subcommittee.

British Medical Journal.

SATURDAY, DECEMBER 12TH, 1925

CONCENTRATED PREPARATIONS OF VITAMINS

THE study of vitamins is passing out of the purely descriptive stage in which the aim of workers was to discover what foodstuffs contain vitamins, and all over the world work is proceeding with the object of isolating these elusive principles in a pure form.

The first successes in this direction were obtained with vitamin B, and some years ago preparations were obtained from yeast of which the vitamin B content was thousands of times greater than that of the original yeast, a few milligrams of these preparations sufficed, for example, to cure pigeons of polyneuritis. Similar successes are now reported with vitamin C, de Zilva¹ and his fellow workers have succeeded in isolating from a litre of lemon juice 0.3 gram of material which they believe contains practically all the vitamin C present in the original lemon juice. This is a three thousandfold concentration, and since a daily dose of about 2 c.c.m. of fresh lemon juice suffices to protect a guinea pig from scurvy, it follows that the guinea pig dose of concentrated principle is less than a milligram. Still more remarkable results have been obtained with vitamin A. Drummond and Coward² have shown that the vitamin A present in cod liver oil can be concentrated into a residue weighing only about 0.5 per cent of the original oil. It is certain that the vitamin only represents a fraction of this residue, and since less than 10 mg. of cod liver oil suffices to promote growth in rats the amount of vitamin A needed as a daily dose by a rat must be of the order of less than 0.01 mg. This is confirmed by the observation of Drummond, Rosenheim, and Coward, who found that 1 mg. daily of irradiated cholesterol was sufficient to promote growth in rats, and that the fraction of the cholesterol altered by radiation was too small to be detected by chemical means.

This concentration of vitamins is of importance in several ways. In the first place, it is of some therapeutic importance, because relatively enormous quantities of vitamins can be given in a single dose. For example, the vitamin C content of twenty or more lemons could be given, if this were thought advisable, to an infant in a single dose in the form of the concentrated preparation. Intensive treatment of this kind may prove valuable as an emergency measure in the treatment of deficiency diseases.

Prevention, however, is much more important than cure in deficiency diseases, and it is to be hoped that spread of knowledge regarding vitamins will soon make deficiency diseases medical curiosities. At present there is no evidence to show that a luxury supply of vitamins is superior to an adequate supply, and hence for routine use as protectives the concentrated vitamin preparations have no outstanding superiority over the ordinary crude sources, and the latter have, of course, the great advantage of being cheaper. The purification of vitamins, which is proceeding step by step, should in time, however, lead to the discovery of their chemical nature, which would be the first step towards their artificial production.

Curiously enough, the biochemists have discovered how to produce vitamin A by means of ultra violet light before they have learnt its chemical nature.

Finally, a knowledge of the quantities of vitamins needed by the body should throw some light on their mode of action. In the case of the rat and vitamin A, for instance, we know that the vitamin need of the animal is proportional to its rate of growth, and that the daily requirement is of the order of one hundredth of a milligram. This quantity appears to be impossibly small, but it can be paralleled among the internal secretions, for example, the amount of adrenaline secreted daily by the suprarenals of a rat would probably be of a similar order. If it should be discovered that the vitamins are some essential precursors of internal secretions which most animals cannot synthesize, just as a supply of iodine is an essential for the production of thyroid secretion, then the smallness of the amounts necessary would at once be explained. This is, of course, a mere speculation, but the minute quantities of the vitamins which are required does suggest that their action is more likely to be associated with the repair of protoplasm than with the metabolism of food.

THE CARE AND CURE OF CRIPPLED CHILDREN

SOME eighteen months ago, in a leading article, we commented on the cripple problem in this country and the efforts made to solve it.¹ We noted that, according to statements in a pamphlet published by the Central Committee for the Care of Cripples, there were only 5,000 beds available for an estimated number of 10,000 cripples who ought to be receiving hospital treatment. Since that time the scheme started in Shropshire by Miss Hunt, and later under Mr. G. R. Girdlestone in Oxfordshire, Berkshire, and Buckinghamshire, has been adopted in other counties, so that at present orthopaedic clinics are at work in twenty out of the forty English counties.

As we then stated, the committee hopes that in the near future every county or group of counties may be equipped with a central-orthopaedic hospital for active treatment, situated in a large town, and with a number of clinics in smaller places which would be visited from time to time by surgeons from the central hospital and by orthopaedic nurses. These clinics are not only to undertake the after care of patients discharged from hospital and the care and maintenance of their instruments and other appliances, but are also to serve as centres to which cases would go for early diagnosis, with a view to their treatment in hospital at as early a stage as possible. The scheme postulates and requires the hearty co-operation of the medical men of the district round each clinic, and this has been freely forthcoming. keen interest and local patriotism in all philanthropic people have been aroused.

After care, however, means more than this. It means help in the education of the cripple in the ordinary schools, and also in the schools for physically defective children, where these exist, and the encouragement of their establishment where needed. The industrial education of the cripple also comes into its purview—the finding out of such work as he or she is fitted for, and the bringing together of the work and the would-be worker. It is manifest that the committee has no small task, already much has been done, but more remains to do.

¹ Dr. Zilva. *Journ. Soc. Chem. Industries* 1925, 44, 445.

² Drummond, Rosenheim, and Coward. *Ibid.*, 1925, 44, 123.

In a new edition of the pamphlet which has just appeared² Mr Girdlestone once more sets forth the projects of the Central Committee, the work so far achieved, and the means by which further progress may be aided. A way in which the scheme could be applied to a county is outlined, and the problem of the teaching of students, with which Sir Robert Jones dealt in his address to the British Orthopaedic Association at Manchester,³ is discussed. The importance and difficulty of the problem of the provision of industrial training for the cripple is considered in a separate chapter. Judging from questions which reach us from time to time, a knowledge of the existing possibilities of teaching a cripple a trade is much desired by medical practitioners. In the County of London every child who has attended a school for physically defective children can obtain such industrial training as he is fit for through the agency of the after care committee connected with that school, but, unfortunately, outside London, schools for the physically defective are few and far between. Of the 62 day schools for physically defective children in England 35 are in London, 7 in Lancashire (of which 4 are in Liverpool), 6 in Yorkshire (of which 3 are in Sheffield), 4 in Essex, 3 in Middlesex, 2 in Warwickshire (Birmingham), and 1 each in Surrey, Reading, Cheshire, Bristol, and Hampshire. In this connection it is worth noting that, under improved treatment and after care, the necessity for schools for the physically defective will probably diminish, for it has been found that 94 per cent of those attending the clinics are able to attend an ordinary school, thanks to efficient hospital and after treatment.

Mr Girdlestone gives also a short account of the methods by which orthopaedic hospitals and clinics can obtain assistance from public bodies, we recommend a study of this to all who are thinking of starting orthopaedic open air hospitals. "Parliament has decreed," he says, "that State funds from rates and from taxes shall be used for the treatment of crippled children and of persons of any age crippled by non pulmonary tuberculosis." This enactment enables help to be given by public bodies to any institution for the treatment of cripples.

In default doubtless of the existence throughout the country of such bodies as the Invalid Children's Aid Association and after care committees attached to schools for the physically defective, the Central Committee has suggested that it might be possible to set up in each area with a central hospital school a committee for the whole area for training and employment. Such a local committee would include representatives from the central hospital, the clinic committees, the juvenile employment exchange, local employers of labour, and the local trade unions. Representatives from each would be able to speak with knowledge of the child, its physical disabilities, its special aptitudes, home conditions, and so on, and the other representatives would supply the knowledge of local trades which the committees might otherwise lack. The Central Committee asked the Ministry of Health if the proposal to set up such local committees experimentally would have its approval and that of the local exchanges. The Ministry replied sympathetically, and as an outcome a conference was held at the Wingfield Orthopaedic Hospital, near Oxford, to discuss plans. It was decided that the City and County of

Oxford Advisory Committee for Juvenile Employment should be asked to appoint a subcommittee on which the Wingfield Hospital was to be fully represented. This subcommittee was instructed to collect information as to the occupations different kinds of cripples could follow, and to take steps to interest employers in finding openings for cripples when discharged from hospital. It is hoped to extend this arrangement to other counties. In the meanwhile the Central Committee for the Care of Cripples⁴ has been making great efforts to deal with such cases as are referred to it from different localities, by giving advice and information about training, and by putting the cripples in touch with the various associations and local agencies which may be able to help them.

It will thus be seen that the problem above referred to, of the provision of industrial training for the cripple, is in a fair way to be dealt with, as has to some extent already been done in London by the After care Association for Blind, Deaf, and Crippled Children.

REFORM OF THE CORONER'S COURT

Reform in the law of the coroner and the coroner's inquest has long been overdue. As it stands to-day it is inadequate to achieve the objects at which it aims, and even within its scope is inefficient, wasteful, and in certain cases inequitable. These facts have long been recognized, but the subject has never attracted public attention commensurate with its importance, and until the last two years the efforts of the British Medical Association to secure reform have found little support. As early as 1905 the Association drafted a Coroners Bill, and in 1909 gave evidence before a departmental committee which had been appointed in the previous year to inquire into the law relating to coroners and coroners' inquests and to the practice in coroners' courts. The committee reported in 1910, and a bill was introduced in April of that year, but was not proceeded with, and the law embodied in the Acts of 1887 and 1892 has remained substantially unmodified, except by certain temporary war legislation which, in the absence of a permanent Act, has been continued from year to year.

After the war the Association resumed its efforts to secure reform, and in 1923 a Death Certification and Registration and Coroners Law (Amendment) Bill was presented on its behalf by Major Molloy. The bill, which lapsed with the session, was not altogether satisfactory, and it was felt desirable to subject a policy, which in all its essential points dated from 1909, to a scrutiny and revision in the light of the experience of intervening years. The result was the adoption this year at Bath of a modified policy. Meanwhile the question had been given much consideration by the Labour party. Private members' bills had been presented by Dr Salter and a group of Labour members, and by Dr Fremantle for the Federation of Medical and Allied Services, neither bill completely covered the ground staked out by the Association, though both dealt with the matter logically as a special section of the law of death registration and certification.

The Government bill introduced by the Home Secretary on December 1st embodies the main recommendations of the departmental committee, supersedes the temporary war legislation, and introduces certain new features of definite value. Hitherto there has been no statutory regulation of the qualifications

² *The Care and Cure of Crippled Children. The Scheme of the Central Committee for the Care of Cripples.* By G. R. Girdlestone. 1925. Bristol: John Wright and Sons Ltd. London: Simpkin, Marshall and Co. Ltd. Price 6d.

³ *BRITISH MEDICAL JOURNAL* October 31st 1925 p. 739.

⁴ The address of the Central Committee for the Care of Cripples is Carnegie House, 117, Piccadilly, London, W. 1.

required for the office of coroner. The general custom in this respect is to be legalized by the provision that in future county or borough coroners and their deputies shall be either barristers, solicitors, or legally qualified medical practitioners of not less than five years' standing in then profession. The franchise coronerships, which have long been a source of waste and inconsistency in administration, are to be abolished as they become vacant, with the exception of those for the King's Household, the Admiralty of England, and the Isles of Scilly, and the only appointing authorities are to be henceforward county and borough councils. The necessary provision is made for the first time for the appointment of assistant deputy as well as of deputy coroners, and for the creation of new coroners districts at the discretion and on the order of the Secretary of State. The rate of salary is to be settled by agreement between the coroner and the appointing authority, or, failing such agreement, by the Secretary of State. Superannuation is to be payable in certain circumstances after not less than five years' whole time service as county or borough coroner, and the appointing authority is empowered to require the resignation of a coroner after not less than fifteen years' service if he has attained the age of 65. The power to dispense with a jury, first conferred by the Juries Act of 1918, is perpetuated, but the exceptions contained in that Act are elaborated and extended, and a jury is in future to be required in all cases where it seems possible that the death has occurred in circumstances the continuance or recurrence of which is prejudicial to the public safety. When any person is charged before the examining justices with murder, manslaughter, or infanticide, before the coroner's jury has given its verdict, the inquest is to be adjourned pending the completion of criminal proceedings. The view of the body by the jury is made optional, and provision is made for holding an inquest in cases of death where circumstances preclude recovery of the body. It is also made possible to secure a rehearing in some cases in which there has formerly been a doubt as to the competence of the High Court under the Act of 1887.

As regards medical witnesses and *post mortem* examinations, the coroner is at last to be empowered to direct and to pay for a *post mortem* examination as a preliminary to deciding upon holding an inquest and irrespective of the subsequent holding of that inquest. He may also call such medical evidence as he thinks desirable, but by a strange anomaly, while the Secretary of State is empowered to make adequate provision for fees payable for certain services rendered under the Acts, this power is not extended to the fees payable under Section 22 of the Act of 1887 in respect of *post mortem* examinations and medical evidence, which are to remain unmodified. As against this piece of economy, the profession will welcome the repeal of the section debarring medical officers of public institutions from receiving remuneration for attending inquests upon persons dying in the institutions they serve. Finally, the Lord Chancellor is empowered, with the concurrence of the Secretary of State, to make rules regarding the procedure in the coroners court—a safeguard which will be particularly appreciated by medical practitioners, who have often suffered from the absence of any such rules.

Those familiar with the policy of the British Medical Association will gather from this brief review that, except at one point, the present bill is in general accord with the principles it lays down. Unfortunately that one point is fundamental. In the view of the Association the confusion of the judicial and

administrative functions of the coroner is unsound, for a judicial inquiry presided over by a person who may have no knowledge of medical science is not an adequate method of ascertaining the cause of death for the purpose of registration. Apart from this, and from those points of criticism proper to a more detailed survey of its provisions, the bill may be welcomed as conferring a generous measure of reform and one which is urgently needed. It is unfortunate that its introduction at so late a date precludes any possibility of adequate discussion in Parliament this session.

THE STANDARDIZATION OF INSULIN

THE fact that the pancreas produces an internal secretion essential for normal carbohydrate metabolism was known for forty years before Banting discovered a method by which this hormone could be extracted. This discovery was the first great step forward, but another fundamental piece of work of almost equal importance was done when it was ascertained that the action of insulin could be determined quantitatively by measuring its action in lowering the blood sugar of rabbits. These two discoveries opened the field for biochemical research, and the rapidity with which this has proceeded is indicated by the fact that in early experiments in 1922 from a kilo of pancreas about 10 rabbit units were obtained, and the product contained only one rabbit unit in 5 to 10 mg of solids, whereas to-day yields up to 4,000 rabbit units per kilo of pancreas are to be got, and Professor Abol of the California Institute of Technology has recently described a new concentrated preparation giving 40 rabbit units per milligram. Moreover, he and Geiling have prepared a product of sufficient purity to enable them to make certain statements regarding its composition. Insulin, they say, does not contain phosphorus, its activity is associated with the presence of sulphur in a highly labile form. This labile sulphur is easily removed by weak alkalis, and when this happens insulin loses its activity. "It is now," the authors say, "only a matter of time, we believe, when this unstable hormone must yield to the investigator the secrets of its composition and the rationale of its operations within the body." Knowledge of insulin will, of course, only be complete when its chemical composition has been ascertained and when it can be estimated quantitatively by chemical methods. Meanwhile, however, what has been learnt about insulin, though limited in certain directions, is proving of inestimable practical value in the treatment of diabetes mellitus. Insulin, however, is far too potent a drug to allow of its use in full therapeutic doses unless a method of reliable standardization is available. The workers at the National Institute for Medical Research at Hampstead have done great service to the medical profession in perfecting the methods of insulin standardization. All methods of biological standardization are difficult, because unfortunately there is no such thing as a standard animal. It will, however, be seen from the accounts published at page 1102 how this difficulty has been surmounted by various refinements of method. It is interesting to learn that at first clinical workers had to rely entirely upon the biological standardization for estimating the activity of the insulin preparations they used. Very soon, however, the clinicians learned the properties of insulin, and were able to estimate the strength of preparations more accurately from clinical observations than could be done in the laboratory. The recent improvements introduced into biological standardizations and described by the workers at the Hampstead institution have removed this reproach from the laboratory, and the laboratory method of assay can now hold its own with the most careful clinical measurements.

This will be a boon to clinicians, since it is of greatest advantage to them to know that the estimated strength of the insulin they use is accurate within the limits of difference that can be observed from therapeutic results

THE LONDON SCHOOL OF MEDICINE FOR WOMEN

THE annual dinner of the London (Royal Free Hospital) School of Medicine for Women was held at the Savoy Hotel on December 3rd, when a company of 400 sat down under the chairmanship of Dr J Walter Carr, consulting physician to the hospital. The principal toast, that of the school and hospital, was in the hands of Lord Riddell, who said that the affairs of the hospital were at present in a sound condition, although, like all such institutions, it was hard up, and needed funds for the better carrying on of its work. He mentioned the splendid service that was being done by the school in turning out so many trained women year after year to show the world what women could do when given the opportunity. Dr Carr, in responding, expressed the general regret at the absence of the dean, Dame Louise Aldrich-Blake, from whom a telegram conveying thanks and good wishes was read. He also spoke of the resignation of Dr May Thorne from the post of honorary secretary of the school. Dr Thorne had followed her mother in this post, and their joint service covered practically the whole period of the school's existence. She was, however, resigning only in order to devote herself entirely to the welfare of the hospital. The number of students graduating from the school during the past year had been 100, by some this might not be regarded as a matter for congratulation in view of the overcrowding in the profession, but he himself considered that the work these women had been trained to do was more needed all over the world now than at any former time. He looked forward to the day when the admission of women to all positions on the staff would be the policy of every one of the London hospitals. The health of the guests was proposed by Mr C A Joll, and a response was made by Miss Ellen Wilkinson, M.P., who said that the school had every reason to be proud of its record of close on fifty years, and that it had done much to assist the change in the general attitude towards the entrance of women upon public and professional careers. While women made the claim of equality with men—a very modest claim, after all—they had no desire to claim similarity, and women had their own special contribution to make to the life of humanity. A response was made also by Professor Yandell Henderson of Yale University, who declared that England still took the lead in respect to the quality and efficiency of the work of her hospitals, and that so far as maternal prosperity was concerned her professors were just as well off as those of America. Dr Chodak Gregory, in proposing the chairman's health, referred to the severity of the school regime at the time when she was a student, and contrasted it with the weak-kneed gentleness of the teachers of to day, but she made it plain that she considered the old Spartan methods the more effectual. Dr Carr, as an old teacher, pleaded guilty to Dr Gregory's "indictment" of the severer methods of other days, and expressed his pleasure at meeting again many of those with whom he had spent the happiest working hours of his life. A very pleasant evening was brought to a close with a dance.

POOR LAW REFORM

THE Ministry of Health recently circulated to associations of local authorities, to county councils, county boroughs, and others concerned the proposals for Poor Law reform which will be incorporated in a bill next session. It will be remembered that the whole question of the Poor Law was exhaustively considered by the Royal Commission which

was appointed in 1905 and reported in 1909. Majority and minority reports were made, differing on various points of considerable substance. A committee known as the Maclean Committee was appointed in July, 1917, and succeeded to a great extent in reconciling the majority and minority reports of the Royal Commission. It recommended the abolition of the boards of guardians and the transfer of their functions to local authorities—normally county and county borough councils—on certain stated lines. The report of this committee was accepted by the Government of 1919. On May 27th last the House of Commons adopted without a division a resolution to the effect that legislation on the lines of the Maclean report should be passed, including "a complete absorption of the existing Poor Law authorities and their functions in the county, borough, and district councils." On that occasion the Minister of Health made it clear that, while the principle of the resolution was approved, he must not be understood as accepting the whole of the proposals of the Maclean report. He added that it was the Government's intention to consider the whole question anew, and, following the precedent set in rating and valuation, to discuss it fully with all the local authorities concerned. Provisional proposals have now been circulated by the Ministry of Health to the authorities concerned as the first step in the process of discussion above promised. Generally they are drawn on the lines proposed by the Maclean Committee, but variations are introduced, especially in the direction of giving greater freedom to local authorities in arranging for the performance of the functions to be transferred. Certain new provisions, aimed at securing the same object, are included with respect to the financial relations between the Ministry of Health and local authorities. The proposals, it is said, are to be regarded as purely provisional, devised to enable local authorities to offer constructive suggestions of a definite and concrete kind. It is proposed to make provision for the co-ordinating of all health services and other forms of public assistance, and for bringing Poor Law relief into closer relation with unemployment benefit. The registration of births, deaths, and marriages will be transferred to electoral registration officers, and vaccination to county councils and county borough councils. There is to be a reform and simplification of the present system of grants to local authorities and of assigned revenues. Health services will be aided by a block grant. A supplementary bill is to modernize the provisions of the Poor Law before its administration is transformed. Under the new scheme county boroughs and counties will be less subject to Whitehall supervision. In London the London County Council is to supervise and control the health services of the metropolitan borough councils, and the duties of the Metropolitan Asylums Board will pass to the London County Council, the staff and property being transferred. The health work of the London County Council is to be assisted by local subcommittees, which may include representatives of the borough councils.

DEVELOPMENT OF THE HOME AMBULANCE SERVICE

THE Home Ambulance Service set up by the Order of St John and the British Red Cross Society has now 384 ambulance stations in the country, and the number of patients carried amounts to some 1,500 a week. The work, as the latest report of the committee shows, is well distributed throughout the country. The demand for the cars is naturally greater in the thickly populated areas, but the returns from the more rural areas which it is specially intended to assist show that the ambulances are serving a very useful purpose. The increasing demand on the service to deal with road accidents has emphasized the need

for skill in first aid on the part of the attendants serving with the ambulances. The handling of patients in the course of their removal from their homes to the hospitals, and vice versa, calls for skill, but doctors or nurses are generally at hand to supervise this work. In road accidents, involving perhaps several persons, it often falls to the lot of the attendants to handle difficult cases without professional supervision. A good deal of harm may be done by unskilful handling. For this reason the committee is now making it a condition of the grant of an ambulance, or the replacing of an existing ambulance when it is worn out, that the working of the car shall be in the hands of members of the order or the society who have received a training in first aid under medical supervision. This not only promotes efficiency in regard to the transport of patients, but serves to extend the number of those who voluntarily undertake to make themselves proficient in the practice of first aid. Both the order and the society state that the grant of an ambulance proves a valuable stimulus to the recruitment of new members, and thus enables them more readily to meet the demand for voluntary workers, not only for attendance at great public gatherings and similar work in time of peace, but for the more serious purpose of preparation for the needs of the country in time of war. Besides the ambulances, the committee also controls an x-ray car, which is available for private patients and cottage hospitals within a reasonable radius of London. The car is well equipped, and the apparatus is so constructed that it can be taken to the home of the patient, erected in the bedroom, and connected by means of a cable with the dynamo in the car. In this work the committee has the advantage of the co-operation of the British Institute of Radiology. The condition, strictly adhered to, that a consulting radiologist shall be responsible for the examination in all cases ensures skilled interpretation of the radiogram. In addition to providing thereby that aid to differential diagnosis which is so important an element in the value of the work, special terms are offered to cottage hospitals which it is hoped will make it economically advantageous to make use of the x-ray car. A number of these institutions already avail themselves of the service of this mobile unit in preference to setting up their own plant, and a considerable extension of this branch of the work is hoped for.

THE MEANING AND PURPOSE OF EVOLUTION

SIR OLIVER LODGE, F.R.S., who was for a short time one of Huxley's students, delivered the Huxley Lecture at Charing Cross Hospital Medical School on December 3rd. Sir Frederick Mott was in the chair, and the subject chosen for the lecture was the meaning and purpose of evolution. Sir Oliver Lodge deprecated the employment of the term "evolution" as the opposite of "creation." The attempt to explain evolution as a self-acting process had some elements of truth, as an intermediary stage in this vast study it was helpful and invigorating, and enlightened the science of biology with a useful working hypothesis, but it had many weaknesses, omissions, and crudities which were now becoming manifest. However rational the recent proceedings in Tennessee, the absurdity did not seem to the lecturer to have been all on one side, and if the old ideas of creation were evoked, so were some of the new ideas of evolution. But the mistake of the "fundamentalists" was in proclaiming that they had an infallible guide, whereas the very documents on which they relied, however rich in inspiration, were very human documents after all. Sir Oliver Lodge's own thesis was that there was no essential opposition between creation and evolution, the one was the method of the other. He proceeded to give, from his own point of view as a physicist, the conception of cosmic evolution which presented itself as the result of

the amazing discoveries in physics during the last twenty-five years. It was necessary first to postulate an all-extensive substance, the ether of space, which here and there, so to speak, was gathered up into knots, the so-called protons or electrons carrying a positive or negative electrical charge. No one could say how the "knotting" of the ether was accomplished, and he had failed abjectly to imitate it in the laboratory, but the attractions and repulsions of these specialized points in the ether were familiar to the first-year student in electricity, they accounted for chemical affinity, for the formation of liquids and solids, for the strength of materials, and for most natural phenomena. The electrons grouped themselves into ninety-two different patterns, and so constituted the atoms of matter, and the atoms joined together to form molecules. Most of the lines of force inside the atom had only a limited power of attraction, and beyond those limits electrical forces were superseded by another force, that of gravitation—a force exhibited slightly in the neighbourhood of bodies of small mass, but in a high degree in the neighbourhood of bodies of large mass such as the earth. In the recently discovered star, the companion of Sirius, which had a similar mass to the sun, but was compressed to about the size of Uranus, the force of gravity was 200,000 times greater than it was upon the earth, and there a gold sovereign would weigh a ton! It was mutual gravitation alone which held together the nebulae, the raw material of worlds, and made them assume an oblate form, so that the solar system had the shape of a spindle, with the larger planets like Jupiter in the middle. The nebula from which the sun arose was proceeding on its course of stellar evolution, and the remains of it were seen in the Milky Way. From the sun proceeded a radiant energy, not perceptibly diminishing, due to the destruction of solar matter consequent upon the clash of positive and negative electricities. At some inconceivably remote period the sun had been a larger and hotter body than now. The radiant energy issued from the sun at the cost of four million tons of matter destroyed every second, and yet in spite of this colossal expenditure the sun's mass was so enormous that this process of destruction could continue for 150,000 million years before the sun lost 1 per cent of its total substance. By the side of the process whereby matter was continually being converted into energy human existence was a flash in the pan. The human race was still in its childhood, but it had risen to consciousness. Apparently the universe must have had a beginning in the formation of nebulae 200 billion years ago, and it must ultimately have an end in the disappearance of matter and the existence once more of pure ether, filled with a perpetual radiation travelling in all directions at the speed of light. Yet it might be doubted whether there need have been a beginning or would be an end. There might be a recuperative process at work even in the physical universe, a formation of matter as well as its destruction. The pressure of light had swept out to the confines of space the cosmic dust which came between one planet and the stars. What if the light might be acting upon that dust in the same energizing way as it was known to act upon vegetation, upon the skin, upon the retina, upon the photographic plate, stimulating the elections in the atom to jump from one stable orbit to another and so begin again the formation of nebulae and the growth of worlds? Creation might well be a continuing process, without beginning or end. It was not to be inferred that there was no progress, that what had been would always be. It was only of the physical universe that he had been postulating this cyclical change and reappearance, there remained the universe of the mind, the soul, and the spirit. The physical universe might follow a cyclical round, energy first taking the potential form, then the kinetic, then the potential again, but in the moral universe there was

growth, development, increase of values, the lower organisms reaching up to man, and for man infinite progress in store

THE FIRST LONDONERS

PROFESSOR F. G. PARSONS, F.R.C.S., was fortunate in his local colour for the lecture which he gave at St Thomas's Hospital on December 4th on the earlier inhabitants of London, for, as he reminded the audience, St Thomas's stands by the site of an ancient ford which crossed from Lambeth to Westminster in the very earliest times, and decided more than anything else the locality of the future metropolis. This ford was probably the most important in all Britain, for it was the lowest point at which the Thames could be crossed otherwise than by boat, and although Caesar did not use it in his conquest—or, rather, his punitive expedition—preferring to cross at places further up the river, it was in existence before Caesar, and was used by the early peoples who made their way from the mainland of Europe and across Kent. Between two and three thousand years ago, said Professor Parsons, the country around what is now London was inhabited by the Long Barrow race, who worked their way up to Britain from the Mediterranean. These were short, dark, slightly built, long-headed people. Only two skulls representative of this race were to be seen in London, one at the Royal College of Surgeons and the other at Guy's Hospital, and he was fortunate enough to be able to show his audience both. These people received their name from the fact that they buried their dead in long barrows, they erected monoliths also, and Stonehenge was regarded as their handiwork. Probably the purest examples of this type of people remaining in these islands to-day were to be found among the miners in the Forest of Dean. Later there came another race into Southern Britain, known as the Round Barrow men, or the Beaker folk. They were of the Alpine stock which covered all Central Europe to-day. He exhibited two of their skulls, one of which he had himself dug up at Broadstairs. These people evidently settled in the neighbourhood of London, for a number of round barrows had been found in Greenwich Park, which was on the site of Watling Street, though, of course, the Roman road was of later date. Apparently the long barrow people lived on terms of fair amity with the round barrow, and intermarried with them. The next people who came into Britain were the Celts, men of the great Nordic race, the third and last of the three great races of Europe, who, up in the Baltic, had become bleached, then hair reddish, their eyes blue or steel-grey, and their skin markedly fair, with the blue veins showing, which gave rise to the expression "blue blood." The first of these Celts to come were the Gaels, who were believed to have passed rapidly to Ireland, Scotland, and the Isle of Man, so that they might be dismissed from the story so far as London was concerned. The Britons came next, reaching this country about 600 B.C., in the later Iron Age, probably they called themselves Cymry, the name still used by the Welsh. Then, fifty years before Caesar, came the Belgæ, who were also of the Nordic race but with some Alpine infusion, and settled in the country north and south of the Thames. The first Londoners, therefore, were a mixture of a Mediterranean race and a Nordic element, with a dash of Alpine blood, they were too Mediterranean and not sufficiently Nordic to make an ideal race, but time was to remedy that disadvantage. The Mediterraneans were a volatile, suspicious, and revengeful people, horn blower and musicians, and fierce though perhaps not stubborn fighters. The Nordics were slower and less gifted, poor at learning speech other than their own, but their qualities were more lasting and they triumphed by reason of their adaptability. They were tribal individualists, whose unit

was the homestead, the Mediterraneans, on the other hand, were communists. The origin of London as a city dated from the early part of the first century, when Cymbeline, who reigned at what is now Colchester, was the outstanding British king. His choice of London was dictated by several good reasons, mostly commercial. In the wake of the Romans came other Continental people—the Franks and Jutes from North Germany, the Frisians from the Netherlands, and the Saxons, in huge numbers, from the mouth of the Weser and the Elbe. The modern Londoner owes something to them all, but which is chief creditor who can tell?

MILK AND HEALTH

THE December number of the *English Review* contains an article entitled "Milk and health" by "A London Physician." The author states that he was inspired to write the paper because he recognized the need for education on the subject, and he quotes Roserum as saying that "Education is one of the principal spokes in the wheel of the milk wagon." After pointing out the importance of milk as a food, noting that too little is consumed in this country, and describing the dangers of contamination with the germs of disease, he discusses the question of pasteurization, and quotes Dr. Eric Pritchard's remarks at the Annual Meeting of the British Medical Association at Bath in July in favour of this procedure, and he sets against them statements made at the National Milk Conference at the London Guildhall. At that conference Professor J. M. Beattie of Liverpool said: "Conn and Hamel admit that *B. tuberculosis* may remain alive even in carefully pasteurized milk. Consequently pasteurized milk, as commercially produced in this country, is often an infective milk." Dr. S. R. Douglas said: "The pasteurization of milk as carried out by the trade in this country is, from the consumer's point of view, absolutely useless." The author favours the use of dried milk, and suggests that future generations may buy their milk in powder from the grocer instead of in can or bottle from the dairyman. At the same time he thinks it certain that, if the public insists, the milkman could supply a much cleaner milk, while boiling would render the present supply comparatively safe. For purposes of education it is, perhaps, unfortunate that the public should have to be told that experts disagree on the methods to be used for producing a safe milk. At the present time it is probably better to tell such members of the public as yearn for clean milk to get their supply from the best source available, to be prepared to pay a good price for it, to put up with pasteurization as an additional, if not complete, safeguard, to be careful about the milk after delivery at their houses, and to leave the experts to thrash out the question of obtaining as clean a supply as possible. Drying milk may be very effective as a cleaning process, but, whatever its merits or demerits in other respects, few will regard it as producing so palatable a fluid as raw milk.

THE PROBLEM OF IMMUNITY

ACCORDING to present-day conceptions the problem of immunity is a cell problem, and no humoral theory in fact exists, yet many of the explanations that are advanced are of a purely humoral character. A reasoned protest against what he considers to be the undue influence that "humoral" phenomena are allowed to exercise in discussions on immunity has been made by Dr. F. M. Lehmann in a recent work on this subject.¹ Ehlich recognized the primary importance of the cell, and considered that our object should be to obtain an insight into cell life by analysing its activities into a number of partial functions.

¹ *Die Lösung des Immunitätsproblems*. Gedanken von Dr. Fritz Michael Lehmann. Berlin: S. Karger, 1924. (Roy. 8vo pp. 208. 8. 10d.)

Thus he endeavoured to do by means of the chemical method, but it was, strictly speaking, merely a tentative experiment, and he would have been the last to adhere tenaciously to a chemical theory, as have some of his followers, who are still trying to isolate antibodies. This deviation into the backwaters of pure chemistry was due, in Lehmann's view, to the fact that the serum reaction was discovered after, instead of before, the reaction to bacteria. The latter reaction was regarded as a defensive movement on the part of the body to an attack by bacteria. With the study of the serum reaction, however, it was found that the organism was as active against its own defensive weapon, the antibody, as against its enemies, the bacteria, and elaborated substances of an anti antibody type, the absurdity of the notions of attack and defence thus became evident. Research has now regained its proper direction, for the problem of immunity is regarded as one of cell life and cell metabolism. Thus, Lehmann considers, as a return to Virchow, whose conception of the cell as a "person" he pushes to its extreme. We are asked to contemplate, not merely the properties of the cell as taught by physiologists, but also to consider its psychology, its free will, its habits, its memory, and so forth. This may appear to be introducing fancy rather than the imagination into scientific matters, but the book is interesting and suggestive, and it also contains much information on the more recent progress that has been made in the subject of immunology. It contains no new facts, and claims merely to point out the direction in which the solution of the problem is to be found, not to furnish the solution itself.

OLD MEDICAL BOOKS

THE many medical men who are interested in the history of medicine may be glad to have their attention directed to a very rare old book which will appear for sale at Messrs Sotheby's, in Bond Street, on December 14th. It is by John Cotta, and is entitled "A Short Discoverie of the Unobserved Dangers of severall sorts of ignorant and inconsiderate Practisers of Physicke in England. London. Imprinted for William Iones, and Richard Boyle 1612." In the same sale is included also a copy of Sir T. Elyot's "Castel of Helthe," which unfortunately lacks the title-page and cannot be dated, as the colophon on the last page is reticent, but the auctioneers aver that this must be a hitherto unrecorded edition, as it does not correspond with the issues of 1541 and 1547. Another volume to be sold the same day contains the 1572 edition of Elyot's book, and three other works on health ranging from 1557 to 1576.

DENTAL DISEASE IN CHILDREN

THE Medical Research Council has issued this week a report by the committee it appointed in 1921 for the investigation of dental disease. The first, by Mr J. Howard Mumme, on the structure of teeth in relation to dental disease, was published in 1923, and was noticed in our columns at the time (1923, vol. ii, p. 388). The new report is on the incidence of dental disease in children, and is founded on the result of the dental inspection of 4,000 children in public elementary schools. It is mainly statistical and is designed to supply data which will be reliable from an etiological standpoint. It was thought that if a number of investigators were employed, although a large amount of information could thus be obtained, the personal equation of each investigator might render difficult the satisfactory comparison of the results. The inquiry was therefore entrusted to one investigator, Mr N. J. Ainsworth, L.R.C.P., M.R.C.S., L.D.S., and the statistical reduction of the data collected was carried out by Dr. Matthew Young, a member of the staff of the Medical Research Council's Department of Statistics. The medical profession is

indebted to both these gentlemen for the careful way they have carried out their laborious task.

The points of inquiry scheduled by the committee comprised (1) The age and period of eruption of the permanent teeth, (2) the most common sites of caries, (3) age of commencement and rate of progress of caries, (4) teeth most frequently attacked, (5) frequency of "arrested caries", (6) frequency of hypoplasia and its relation to caries, (7) incidence of chronic marginal gingivitis, (8) frequency of antero posterior mal-occlusion.

That a very large amount of material can be collected by a single observer is shown by the fact that Table II, a summary of the incidence of caries in permanent teeth, is compiled from observations on 55,000 teeth. Yet the committee has to acknowledge that on some, and by no means unimportant, points the material is insufficient to allow of definite deductions. Such points are the possible influence of race on caries, the relative incidence of caries in town and country schools, and a comparison between the various schools examined.

In regard to the main issues, the committee thinks that "the replies to the original questions are definite, and may on the whole be considered reliable." The data on eruption confirm previous conclusions. Those on the incidence of caries in permanent teeth show no sex difference and confirm the bad reputation of the first permanent molar as showing the highest percentage of caries. If, however, the incidence of caries is calculated for each tooth at one year after the average date of eruption, then the lower second molar has the highest incidence, and the lower first molar, upper first molar, upper second molar, upper first premolar, upper central, and upper lateral follow in a descending scale, giving a valuable indication of the relative liability of these teeth to caries. "Arrested caries" is very rare among permanent, but comparatively common among temporary teeth. Hypoplasia increases the incidence of caries.

The slighter forms of gingivitis occur in about one-third of the children examined, and there is a steady rise, with increasing age, in the numbers with the severer forms of the disease. Some degree of antero posterior mal-occlusion was found in 23.2 per cent of all children examined. The occlusal surface is the most frequent site of incidence of caries especially among the molar teeth.

Such are, shortly, the committee's conclusions, but there are many other points of interest on which light is thrown in the report. We may note, as two such points, the infrequency of syphilitic hypoplasia, and the very slight indication that softness or hardness of water has an influence on dental caries. That no conclusion could be reached in regard to the time of onset and rate of progress of caries is not to be wondered at, but figures on the matter given in Table V point to a possible elucidation of the problem.

The report will make a strong appeal to statisticians on account of the accuracy of its figures and the explanatory notes accompanying the diagrams.

We may be allowed to ask whether in actual fact as the specimen chart indicates, only "anterior marginal gingivitis" was considered. If we add that in one or two places the train of thought in the minds of the framers of the report is not quite clear we have expressed our worst criticism. The report is a valuable record of accurate and carefully considered observation, none the less valuable for the fact that its whole tenor confirms the prevalent views of the etiology of dental caries.

SUBSCRIPTIONS FOR 1926

MEMBERS of the British Medical Association are reminded that subscriptions fall due on January 1st in each year, and that if each member who receives an application for his or her subscription from the Head Office will send the amount to the Financial Secretary within the first week of the new year the work of the office will be very considerably lightened. Members are also reminded of the claims of charity. The amounts at the disposal of those concerned in the administration of medical benevolence are altogether insufficient to meet the appeals that are received, and the British Medical Association Charities Fund was formed in order to assist. Subscriptions or donations are urgently needed, and every member of the Association is asked to add to his next payment a sum for the credit of the Medical Benevolent Account.

THE BUILDINGS OF THE UNIVERSITY OF BIRMINGHAM AT EDGBASTON

THE CENTENARY OF THE BIRMINGHAM MEDICAL SCHOOL

THE centenary of the foundation of the Birmingham Medical School was celebrated on Tuesday, December 8th in accordance with the programme sketched in the article published last week (p. 1071) when an account was given of the history of the school. In declaring the congregation open the Vice-Chancellor, Sir GILBERT BARLOR, Bt. C.B., F.R.C.S., expressed the regret of the Chancellor Viscount Cecil, that he could not preside owing to his being required to attend a meeting of the League of Nations at Geneva.

Honorary Degrees

The Principal of the University, Mr. C. GRANT ROBERTSON, in a short address, said it was a happy circumstance that the twenty-fifth anniversary of the foundation of the University of Birmingham should have coincided with the centenary of the Medical School, which was now the Faculty of Medicine. It was appropriate that the ceremony should be taking place in the University Hall, which was both a testimony to, and a memorial of, the first chancellor, Mr. Joseph Chamberlain, and of those who had worked with him. The munificent gift of £100,000 made to the University by Sir Charles Hyde, proprietor of the *Birmingham Post* and the *Birmingham Mail*, would make possible the realization of some ideals it was urgently desired to carry out. The donor, while leaving the University free in its disposal of the gift, had made certain suggestions, including the establishment of a Students' Union, the extension of the men's hostel, Chancellor's Hall, the improvement of the library, and research work.

Honorary degrees of Doctor of Laws were then conferred by the Vice-Chancellor. In presenting Mr. Neville Chamberlain the Principal said that he was one whose services to the University and the nation justified the heritage and traditions of his name and family. In presenting Sir Donald MacAlister, President of the General Medical Council since 1902, and Principal of the University of Glasgow since 1907, the Principal said that he had required a knowledge of almost as many languages as there were names in the *Pharmacopoeia*. Sir Humphry Rolleston's position was indicated by the two offices he held—President of the Royal College of Physicians and Regius Professor of Physic at Cambridge. In presenting Emeritus Professor Priestley Smith it was said that he had three claims to recognition—first as an educationist and teacher of ophthalmology, secondly as an ophthalmic surgeon, and thirdly as a man of science, who by his

original researches, particularly on glaucoma, had earned a world-wide reputation.

Mr Chamberlain's Address

Mr. CHAMBERLAIN began by saying that it was nearly forty years since he entered the Mason Science College, and twenty-five since he became a member of the first council of the University in which that college was now merged. The University was about to make extensions which would carry it a step further toward the completion of the original design of the buildings at Edgbaston. Each addition to the building necessitated extensions in other directions—in staff and equipment, and increased annual expenditure. In the Medical School he was bound, as Minister of Health, to take particular interest. It was one of the duties of the Minister of Health to survey the medical needs of the country, to consider what means were available to meet them, and to fill in any gaps which might exist in the organization for the protection of public health. The value of that vast organization, coupled with the private services that completed the country's system of curative and preventive measures, was not a fixed, unchanging quantity, it depended upon the personality of those engaged, upon the power of the whole organization to attract the best material, and upon the training and influences that acted upon that material. If the stream of new candidates was allowed to wither in quality or dry up in quantity, if the profession was to get rusty and out of touch with modern ideas, then the whole value of the health organization would disappear. To prevent such a catastrophe it was necessary to provide and maintain medical schools adequately equipped and efficiently managed. Such a city and centre as Birmingham must have its own medical school, it provided a training ground for students which was within their reach, a fact of importance from economic as well as other points of view, and the presence of teachers and students in the hospitals, had a beneficial effect upon them. Further, the existence of a medical school afforded in the hospitals, in the laboratories of the university, and in the medical societies, an opportunity of post-graduate work. Last, but not least, was the research work done in the laboratories of the medical school. These researches were concerned with a large number of different subjects, there was in Birmingham a board of research in cancer, composed of representatives of all the hospitals, together with some of the professors of the University. In this inquiry team work was necessary, and the more places in which such researches

were carried on the greater was the probability of arriving at a speedy solution. A second line of investigation in Birmingham was into the relation between diet and dental caries, and there was also a Birmingham Board of Mental Research, working to bring the treatment of mental disease into the general field of medicine. Birmingham was fortunate in having a medical school of considerable antiquity and distinguished history. It was only on the threshold of its career, for there lay before it new work in directions which could hardly be foreseen.

In the evening a reception and entertainment in the University buildings at Edgbaston was attended by some 2,000 guests, who were received by the Vice-Chancellor and Miss Billing, by the Principal, and by the Dean of the Faculty of Medicine, Mr. W. F. Haslam, F.R.C.S.

THE HEALTH OF THE SCHOOL CHILD

(Concluded from page 1028) -

DENTAL DISEASE

An important section of the Annual Report of the Chief Medical Officer of the Board of Education is that dealing with the prevention of dental disease. Of 1,766,325 children examined by the school dentists last year, no fewer than 1,187,335, or 67 per cent, were found to require immediate treatment, and half of them received treatment. The variety of work done is shown in a table. There has been an increase of nearly 35 per cent as compared with the two previous years, but it is estimated that to cope with the work that should be done the number of school dentists ought to be the lowest estimate to be tied. Besides the permanent clinics, there are now a number of temporary ones which are set up as conditions require.

An investigation has been carried out, under the auspices of the Medical Research Council, on the incidence of dental disease in school children which reveals some interesting facts as to the origin and course of caries. It was found that generally disease arises in fissures or pits, or on the surfaces where teeth come into contact with each other—places, in fact, where cleansing is difficult. Of the importance of the prevention of caries there can be no question. An approved society which provides dental treatment for its members obtained a reduction of over 40 per cent in the number of sickness claims for anaemia, gastritis, dyspepsia, and rheumatism. The first step in prevention must be the dispelling of ignorance. Parents should be instructed. They should learn that the permanent teeth are worth preserving, that neglect of the milk teeth endangers the permanent, that decay once started will mean loss of the tooth unless it be treated. The popular view that extraction is better than mending is to be combated. Many districts are undertaking educational work. In London the dental inspection is the occasion of a short address to the assembled parents and a personal explanation of what should be done for each child. At the dental clinics the same procedure is adopted.

DEFECTIVE CHILDREN

The number of children with special defects returned by the local authorities last year showed an increase from 148,602 to 170,167. This does not necessarily mean an increase in defectives, but that the authorities were more intent on their duties. So far as blind and deaf are concerned, it would appear that the tails of these children are known. But there are large numbers of physically and mentally defective children who are not known to the authorities. There is need for a speedy increase in the provision for orthopaedic cases, early attention would be in the highest degree profitable, and there would follow a material diminution in the need for cripple schools. Arrangements between school authorities and voluntary hospitals for this purpose are being increased all over the country with the best results.

Mental defectives are a serious problem. The number of these children, the high cost of special forms of education required by them, the poor results that are to be obtained from such poor material, all lead to the question: Why not bank our limited resources of money on the child whose education is more remunerative? The reply to this ques-

tion is given somewhat in this fashion. Neglect of these children means that they will either be left in the ordinary schools where they will act as a dead weight upon the work of the normal children, and eventually become a heavier charge upon the State. There is no way of avoiding these results save by the provision of such training as they are able to receive. The blind, deaf, and physically defective respond in an exceptional degree and become good and useful citizens, able to compete with the normal, and even one third to one half of the mentally defective are so much improved that they subsequently become contributors to their own maintenance and are safeguarded from most of the evils inherent in their condition.

INFECTIOUS DISEASES

Infectious diseases are the principal cause of the child's absence from school. Of all infectious diseases, except tuberculosis, diphtheria is the most deadly at school age, measles comes next, followed by scarlet fever, then whooping-cough. Tuberculosis has a mortality rate twice as heavy as diphtheria. The notifications of diphtheria at all ages in 1924 numbered 41,980, as compared with 66,500 in 1921. It is thought that the time is ripe for considering the question of the desirability or otherwise of making the Schick method of protection against diphtheria more generally available to the child population of this country. Its value is fairly assured, details may be improved, but experience at Edinburgh clearly showed that a large proportion of parents, when properly approached, were not only willing but eager to permit the application of such methods of protection to their children.

HEALTH EDUCATION

It is roundly stated that much of the teaching in hygiene is comparatively barren and unprofitable. The first reason is that it is devised without sufficient regard to the fundamental principles of education. To be effective it must be a continual process in the whole school life so that it becomes an habitual right outlook—a health conscience. It must be concrete and obvious, a personal affair involving the child, the home, and finally the community. The school premises must reinforce the lesson by good example. Hygiene can never be taught in a dirty, ill-ventilated, and ill-lighted school. The foundation of the teaching should not be a set lesson in "hygiene" fixed in the curriculum. It should be interwoven with the regular teaching of elementary science, whether nature study, biology, gardening, chemistry or physics, history and geography, physical training, and the teaching of civics. Biology should be less the teaching of dissections and the study of "types," and more the study of living matter and life processes, so that the oneness of physical life may be shown in the common processes of respiration, excretion, reproduction, and the like. This union of biological and health teaching would provide a sound foundation for natural, wholesome, and progressive education in sex. Teaching in regard to foods and food values should be linked with simple teaching in citizenship, including marketing of provisions, the working of allotments, and milk supply, with visits to dairies, farms, and markets. Even geography may be made to serve in the study of the foodstuffs of other countries and the dietaries of other races. Vitamins can be realized better in a history lesson on Captain Cook and his sailors than by the mere statement of fact. Further, there is need to create a public health conscience which regards as "bad form" the spreading of influenza at a cinema, the wasting of water, the unnecessary picking of other people's nerves by noise, the indiscriminate disposal of rubbish. In this connexion too little appeal is made to the schoolboy in his plastic years. Excellent work is done in this regard by the Boy Scouts and similar organizations. In some parts of the country it has been arranged to teach household matters to boys, and the example set by Essex in the provision of the "handyman" course is one that might be widely followed. In that course boys are taught practical house repairs, model making, and the like. Under water supply they learn how to clean a cistern, repair taps, clean gullies, and remedy defective ball-valves. They are taught how heating and ventilation of rooms is arranged, and the use of coal, gas, electricity, and oil in cooking,

* Articles dealing with this subject were published in the JOURNAL for November 21 (pp. 964 and 971) and in that for November 28 (p. 1077).

They repair sash cords, whitewash and distemper walls, and set up the domestic clothes-lines.

It is suggested that the elder children should be brought to know something of the work of local bodies. To begin with, they might be told the part played by school doctor, sanitary inspector, school nurse, and health visitor, and the relation of these to the public body their parents help to elect. But to get all this excellent work done satisfactorily the training must begin with the students in training colleges.

The report concludes with a chapter on investigation and research. Many school medical officers find time to carry out some special inquiry as a part of their regular work. This practice is commended. "It is of great benefit to the preservation of keenness and efficiency in the medical officer if he arranges always to keep on the stocks some piece of special work of this kind." And the hope is expressed that the local education authorities will consider the advantage of encouraging their medical staff to do this work as a necessary and integral part of their duties. Last year many such pieces of work were done, and of these a list is given. There is also a most useful appendix, giving a list of references to the more important paragraphs and chapters that have appeared in this connexion in the reports between the years 1908 and 1923.

England and Wales.

THE LANCASHIRE AND CHESHIRE SOCIETY FOR THE FEEBLE-MINDED

THE report for 1924 of the Lancashire and Cheshire Society for the Permanent Care of the Feeble-minded contains a note of a speech made at the annual meeting in which Miss Mary Dendy, the president, whose pioneer work on behalf of the feeble-minded is well known, gave an interesting retrospect of her experiences in connexion with the establishment and development of this society. She was co-opted to the Manchester School Board in 1897, and spent a good deal of time in the schools and playgrounds, where she was struck by the number of children who were unable to hold their own either at work or play. With the help of Dr Henry Ashby, to whom Dr Woodcock, well known to many old members of the British Medical Association, gave her an introduction, an examination of all the children under the Manchester School Board was made, and a report later presented. This inquiry had proved the absolute necessity of a permanent home for defective children. A committee was got together and the society formed. In 1902 the first house of Sandlebridge was opened, since when the work had kept on extending. Miss Dendy rejoiced that the board had been strengthened by the addition of young and vigorous people. There was no work, she could assure them, to which they could give themselves that was better worth doing. It was hard work, difficult, and harassing, and not attracting public sympathy as did work for the blind and crippled, but there was no work so absolutely essential for the salvation of the nation. Miss Dendy appealed for voluntary gifts for the upkeep of the buildings and for the necessary extensions. Week by week admission had to be refused to children urgently needing care. The institution now provides for life for 320 persons—212 men and women who have been there from an early age, and 108 children. The work at Sandlebridge was one of the pioneer movements which led to the legislation of 1913. It is conducted under the certificates of two Government departments—the Board of Control and the Board of Education. The Board of Control deals with mentally defective children under 7 years of age, non-educable mentally defective children between 7 and 16 years of age, and all mentally defective persons over 16. The Board of Education, through local education authorities, deals with the ascertainment of mental defect, the determination of educability, the provision of educational facilities, and the notification of custodial cases to the local authorities under the Mental Deficiency Act. Subscriptions and donations may be forwarded to the honorary treasurer of the society, 72 Bridge Street, Manchester.

TUBERCULOSIS ARRANGEMENTS IN LONDON

At the meeting of the London County Council on December 1st the Public Health Committee reported that, after a careful review of the arrangement for the assessment of contributions towards the residential treatment of tuberculosis under the Council's scheme, it was of opinion that the principle of contribution, where the circumstances of the case justified it, should be adhered to, and was satisfied that the existing arrangements were equitable in their operation and worked smoothly and satisfactorily. Dr Stella Churchill moved an amendment that no contribution should be required by the Council in respect of residential cases of tuberculosis under the Council's scheme, whether of children or adults, but the amendment was defeated, and the proposal of the committee to retain the principle of contribution was agreed to by a large majority. The chairman of the Public Health Committee pointed out that under the Act of 1920 sanatorium benefit ceased, and the position of insured persons with regard to the institutional treatment of tuberculosis then became the same as that of non-insured. Family circumstances would be taken into account in determining the amount of the contribution, if any, to be asked for, and he was satisfied that the assessment as carried out under the Council's scheme would not conflict with the interests of public health.

Scotland.

CLINICAL CLUB FOR GENERAL PRACTITIONERS

At a meeting of the Edinburgh and Leith Division of the British Medical Association, held on November 24th, it was decided to form, under the auspices of the British Medical Association, a clinical club for general practitioners. It was pointed out that while numerous societies existed at which special branches of medicine were discussed, and at which scientific papers were read, there were, at the present time, no societies in Edinburgh at which general practitioners could discuss subjects which interested them from a practical rather than from a scientific aspect. It was suggested by one speaker that such a society should be one of the general practitioner, for the general practitioner, and by the general practitioner, although the specialist might be invited to come and give his views on matters affecting general practice, and, it might be, to receive instruction from hearing the views of the general practitioner. The proposal, after discussion, was unanimously adopted, and a committee of general practitioners was appointed to make the necessary arrangements for the formation of this society, under the auspices of the Association, and to call an inaugural meeting at an early date.

LIGHT TREATMENT

A report on artificial light and x-ray therapy, prepared by Dr Lewis D. Cruickshank and Dr Ernest Watt, two of the medical officers of the Scottish Board of Health, has just been issued. It is mainly concerned with the experience gained in Scotland in regard to treatment with ultra-violet radiation and x-rays. It is pointed out that the use of ultra-violet rays in treatment was introduced by Finsen in 1893 for lupus. Finsen began by using solar rays, but the irregularity of bright sunlight led him to resort to artificial sources. On clear days, at an altitude of 8,000 metres, about 75 per cent of the ultra-violet rays penetrate the atmosphere, at sea level some 50 per cent, and in smoky cities the reduction is still greater. In the High Alps heliotherapy has been more successful than is possible in Scotland, and this appears to be due both to the greater amount of ultra-violet rays available and to the fact that these are reflected from the snow. Treatment by the sun's rays has advantages over artificial light, although the latter is in practice more readily obtainable. Experience seems to have shown that the value of ultra-violet radiation is mainly limited to conditions of growth and of function below normal. It increases body weight, and the rate of growth improves the functional activity of the endocrine glands and augments the bactericidal power of

the blood where these are below normal, although it has no corresponding effect on normal individuals. Good results have also been obtained by irradiation of foods, including dried milk. The reporters state that the simple carbon arc and the mercury vapour arc are still the two main sources of ultra-violet radiation. The apparatus is cooled in some instances by air and in others by enclosing the quartz burner in a metal jacket through which water slowly circulates, the rays pass through a quartz window which absorbs them only to a very slight extent. For general clinical work the report recommends an unenclosed lamp of the mercury vapour type, which costs £40 or less and requires a current of 3 to 5 amperes. The unenclosed lamp makes it possible to treat a number of patients at one time. The tungsten arc does not appear to be so popular in Scotland as those already mentioned, partly on account of its expense, and partly on account of the fumes given off in use. In certain cases—in lupus, for instance—local treatment is used, the rays being focused on a desired spot by means of a quartz lens, but general irradiation is much commoner. Part of the patient's body is exposed at first, and the area and duration of the exposure are steadily increased until occasionally the whole body is exposed for a maximum of four hours at one sitting, the patients wearing only a loincloth and tinted spectacles to protect the eyes, and turning round every fifteen minutes or thereabouts, 3 feet is a common distance. The number of exposures given depends on individual judgement, and difficulty in determining the dose arises from the fact that the skin reaction varies greatly in different individuals. Fair persons develop erythema specially readily from exposure either to bright sunlight or to ultra-violet rays, and the degree of pigmentation is a valuable index of the good resulting from irradiation. The report mentions some clinics in which an occasional dose of x rays is given in place of one of ultra-violet rays, and the results of these combined treatments are said to be good in certain cases—for example, lupus, psoriasis, and scabies. Ultra-violet radiation has been found particularly useful in non-pulmonary tuberculosis, especially where there are open lesions or discharging sinuses. In rickets irradiation has been found to be the most valuable single remedy at command, malnutrition in children is also benefited by irradiation. The field of child welfare, in the opinion of the writers of the report, is a very promising one for the use of ultra-violet radiation, and it is recommended that direct encouragement should be given to all the larger child welfare clinics to provide this form of treatment for children suffering from debility, anaemia, delayed convalescence, and the like. It is suggested that some of the larger education authorities might install light treatment in one of their special schools under direct medical control and supervision. An air-cooled mercury vapour lamp with atmospheric burner and without any enclosing metal case is suggested as most suitable for this purpose. Attention is drawn to the good results that have been obtained in Aberdeen from sunlight baths by taking groups of mothers and children to the sea beach and to four of the public parks during the month of June, and it is suggested that in the winter months an arrangement might be made for artificial sun baths. Attention is also drawn to the excellent results which have been obtained at the Motherwell child welfare clinic in cases of rickets treated by carbon arc and mercury vapour lamps combined with the administration of cod liver oil. The changes produced in the bones of the children have been confirmed by repeated x-ray examination, and good results were in most cases noted in so short a space of time as a fortnight. With regard to the clinical uses of x rays, the report states that excellent results have been obtained in the treatment of skin diseases, such as ringworm, psoriasis, eczema, warts, corns, pruritis, acne, and dermatitis, as well as in tuberculous conditions such as lupus and glands in the neck, and in Hodgkin's disease, leukaemia, exophthalmic goitre, and uterine fibroids, while deep x-ray therapy is much used in the treatment of deep-seated malignant growths. The reporters do not, however, consider it necessary to recommend any new installations for therapeutic purposes so far as x-ray work is concerned.

EDINBURGH INFIRMARY LEAGUE OF SUBSCRIBERS

The seventh annual general meeting of the League of Subscribers to the Royal Infirmary of Edinburgh was held on December 1st. Mr James Campbell presided, and Mr Russell Paton, organizing secretary, in his report, stated that the returns for the financial year to October 1st last showed subscriptions amounting to £21,356, received from employees engaged in public works, business establishments, staffs of schools, banks, and Government offices, this was an increase of £451 over the contributions of the previous year. The subscribers included a total of 1,394 groups, of which 1,021 were in Edinburgh. The leading contribution was that of the London and North Eastern Railway Company's employees (North British Railway Section), who had subscribed over £2,490. The employees of the North British Rubber Company had subscribed £700, and those of Saint Cathbert's Co-operative Society £660. Sheriff G. L. Crole, K.C., who delivered an address upon the work done by the Royal Infirmary during the past year, said that the number of patients treated in the wards had been 15,755, an increase of 68, while the number of out-patients had been 55,300, an increase of 7,000 over the number for the preceding year. He believed these were the largest figures treated in any hospital in Great Britain. In addition to these, 1,573 patients had been treated in the convalescent house, and 182 female patients had been received in the Astley-Ainslie Convalescent Home, which was developing into a very large institution, its directors were on the point of erecting the main building of this institution, which was set apart entirely for convalescent patients from the Royal Infirmary. When completed it would accommodate 150 patients and would have a marked effect in clearing the wards of the Royal Infirmary and making room for urgent cases. The waiting list for the Infirmary was over 2,000, which was far too large, although it was true that this represented in great part patients waiting for operations in the ear, nose, and throat department. The income of the Infirmary in the year just ended had reached almost £110,000, which was an increase of over £2,000 as compared with the previous year. Expenditure had been kept to much the same figure as in the preceding year, the total sum being £127,750, an increase of £215. He claimed that these figures were a triumph for the voluntary system. Several extensions of the Infirmary were in active progress. An extension of the ear, nose, and throat department costing £17,000 was to be opened early in the year. The new radiological department, which was to be opened in March, would be, the managers were assured, the finest radiological department, not only in Great Britain, but in Europe. The amount of money involved for the building would be £40,000, with £12,000 for equipment. The Rockefeller Trustees in America had given the University £25,000 to erect a clinical laboratory on condition that it was erected in the Infirmary grounds. It was hoped that, in the near future, the Infirmary would extend its borders over ground belonging to the Merchant Company, and at present occupied by George Watson's College. The report of the departmental committee on hospital inadequacy was read with interest. It was hoped that it would not recommend any interference with the Infirmary, but there were two ways in which the State could help the hospital without affecting the voluntary basis: these were by giving grants for capital expenditure and also to help in research.

EDINBURGH HOSPITAL FOR INCURABLES

The report presented to the annual meeting of the Royal Edinburgh Hospital for Incurables, which was held on November 27th, Sir Henry Cook, chairman of the board of management, presiding, stated that 329 patients had been treated in the Longmore and Liberton Hospitals during the past year, the daily average under treatment being 199. The ordinary income for the year had been £12,071 and the ordinary expenditure £18,594. The expenditure, therefore, had exceeded the income by £6,523, the balance being met out of capital. The average cost per occupied bed was approximately £84, as against £82 in the previous

year Professor G. Lovell Gulland, President of the Royal College of Physicians, gave an address in which he referred to the usefulness of hospitals intended for special purposes. An important gap had recently been filled by the institution of the Astley-Linslie Hospital, which would fill a place intermediate between the general hospital as it existed in the Royal Infirmary and the hospital for incurables, such as the Longmore Hospital. Cases which could not be kept in the infirmary, but which it was believed would get better after a prolonged time with proper care, were handed over to that hospital. The Longmore and Liberton Hospitals for Incurables filled a most important place. A class of human beings for whom all had the greatest respect and sympathy was the nummured daughter or daughter who gave up their lives to looking after their old mothers and fathers, and who awoke when they were about 50 to find their occupation gone and nothing left to take its place. The Longmore Hospital set very many of these free to lead more useful and happy lives than they otherwise could do. He was struck by the sameness of cases in its wards, which included rheumatoid arthritis, disseminated sclerosis, paraplegia, and, of course, cancer. Tuberculosis was becoming more and more a curable disease, and it was hoped in time to banish it from the country. With regard to the others, he saw no reason against hoping that they too might be prevented. He was inclined to hope that the gap at the other end of hospital work might some day be filled by hospitals for the prevention of diseases, so that institutions for incurables might disappear, and funds and buildings be devoted to prevention rather than to treatment. Something had already been done in this direction in regard to tuberculosis, venereal disease, and child welfare. The atmosphere of hopefulness which was now present did not exist fifty years ago.

GLASGOW DISTRICT NURSING

The fiftieth ordinary general meeting of the Glasgow District Nursing Association was held in the Merchants' Hall, Glasgow, on November 25th. Lord Provost Montgomery presided. The report stated that during the year 1924-25 the nurses working under the association had treated 5,334 cases, and the directors felt that if the public realized fully the value of a district nursing association in a large city like Glasgow, the funds necessary for its maintenance and extension would be easily obtained, the ordinary annual income had always fallen short of ordinary expenditure, and in the year under review it had fallen short by £2,198. The Countess of Mar and Kellie, in proposing a special appeal for support, said that the public took it for granted that the nurses were part and parcel of the community, and they did not think how much it cost to train them and what a large measure of responsibility rested on those who organized the training and nursing. If sufficient funds were forthcoming to provide more nurses, 10,000 cases could be dealt with in Glasgow every year instead of about 5,000, and the larger number would be more in accord with those who demanded nursing services and nursing care. Sir John Macleod, Bt., also paid tribute to the work of the association and appealed for greater support.

PROPOSED HOSPITAL FOR INVERNESS

A public meeting was held in the Town Hall, Inverness, on December 1st, to consider a proposal to make additions to the Inverness Northern Infirmary at a cost of about £100,000. The chair was taken by the Mackintosh of Mackintosh, who said that he was sure that this money would be subscribed by Highlanders at home and abroad for the purpose of erecting an up-to-date hospital for the Highlands. A resolution was adopted to request the directors of the institution to go on with a scheme which had been prepared by Dr. D. J. Mackintosh, medical superintendent of Glasgow Western Infirmary.

PENSIONS FOR NURSES

At the thirty-third general meeting of the Glasgow and West of Scotland Co-operation of Trained Nurses held on December 3rd, it was reported that 2,341 cases had been attended during the year by nurses belonging to the institution and that the amount earned by the nurses had been £26,726, since the establishment of the body in 1894,

51,939 cases had been nursed at a cost of £369,199. It has been decided to inaugurate superannuation and pension funds for the nurses and, in order to give the scheme a good start, it was intended to place the interest accumulated from different funds to the credit of this scheme.

CENTRAL MIDWIVES BOARD FOR SCOTLAND

The examination of the Board, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, has just concluded, with the following results. Out of 151 candidates who appeared for the examination 137 passed. Of the successful candidates, 36 were trained at the Royal Maternity Hospital, Edinburgh, 41 at the Royal Maternity Hospital, Glasgow, 5 at the Maternity Hospital, Aberdeen, 10 at the Maternity Hospital, Dundee, 12 at the Queen Victoria Jubilee Institute, Edinburgh, and the remainder at various recognized institutions.

At a special meeting of the Board for the hearing of penal cases (Dr. James-Haig Ferguson in the chair) a certified midwife was cited for failure to send for medical assistance in a case of ophthalmic neonatorum, failure to take and record the pulse and temperature of patients, and for other breaches of the rules. Miss Baker, assistant inspector of midwives for Glasgow, was present in support of the charges. The Board found the charges to be proved, and instructed the secretary to remove the name of the midwife from the roll and to cancel her certificate. Another certified midwife appeared in answer to charges of having neglected to send for medical assistance in a case of haemorrhage, failure to take and record the pulse and temperature of the patient at each visit, failure to attend for the full time during the lying-in period, and other breaches of the rules. The Board found the charges proved, but, in order to give the woman charged an opportunity of proving amendment, final decision was postponed to allow of receipt of reports at the end of three months from the local supervising authority on her conduct and methods of practice, and also at the end of six months. Pending satisfactory reports being received her name was instructed, *ipso facto*, to be removed from the roll.

Ireland.

THE ULSTER BRANCH

THE ULSTER Branch of the British Medical Association held the opening meeting of its new session on November 18th in the Medical Institute, Belfast. Professor MacLellan introduced Dr. D. P. Grussen, Dunmurry, the president for the year, who gave his address entitled "Some advances in scientific medicine during the past forty years." Dr. Grussen pointed out the great progress of the British Medical Association since its inception, and how the Ulster Branch had fulfilled its function of spreading medical knowledge and promoting social intercourse and a *esprit de corps* among the members. He then gave some of his recollections of early pre-Listerian antiseptic surgery, when pus was "laudable," to open the peritoneum was fatal, and when patients died of perityphlitis. He next reviewed the rapid change to the practice of the present day, remarking that now the whole aspect was altered: microbes, vaccines, serums, internal secretions, biochemical tests, x-ray examinations and treatment, electro-cardiograph examinations, and psychoanalysis were dominant. Formerly alcohol held a prominent place in treatment and elaborate rules were assigned for its administration, whereas now it looked as though it were fast becoming a vanishing quantity, instead of ten, fifteen, even twenty ounces of whisky in pneumonia and acute fevers, hypodermic injections of caffeine were given. Preventive medicine had done wonders instead of a death rate of 21.4 per 1,000 (1875-80) it was 11.9 in 1923. Typhoid had disappeared, or was disappearing, and the public were being educated in hygiene. Much of this was due to the medical man becoming a missionary of health. Myxoedema and diabetes might be cited as the reward of original research. Much, however, still remained to be done. Calmette's new vaccine in children

predisposed to tubercle, the now specific antitoxin for scarlet fever, and the discoveries in cancer, all showed that there were new fields to conquer, but knowledge of the cause had always been far ahead of ability to cure. Dr. Gussen then gave some of the latest statistics from Calmette, and discussed the demands for a healthier maternity and lessened mortality in childbirth, with greater hospital accommodation. Finally, he emphasized the fact that nothing did away with the importance of the medical man's personality, as illustrated by the later psychology. Dr. Loughridge proposed a hearty vote of thanks to the president for his address, which was seconded by Dr. Morrow, and passed by acclamation.

Mr. Geoffrey Jefferson, M.S., F.R.C.S., of Manchester, then contributed a short paper on surgery of lesions of the nervous system. He confined his remarks to cerebral tumour, and chiefly to cerebral tension. He referred to the rapid proliferation of bone at the sutures in cases of dilatation due to cerebellar tumour. Vomiting was a very inconstant sign, headache was meningeal, great pain was caused as soon as there was any dragging on the meninges in cases where a local anæsthetic was used, and reference was made by the patient to the forehead and behind the eyes, any increase of tension, as in coughing, increased the headache, and vascular depletion relieved it. Optic neuritis was still not precisely known, if toxic it should be constant, but it varied with position of the tumour, a small tumour might cause it, and it might be absent with a very large one. Venous congestion and cerebrospinal fluid pressure were also causes, in the latter the base of the third ventricle might be depressed. Injection of air was a difficult technique, it showed whether the ventricles were displaced to one side. Numerous lantern slides, illustrating the various points in the paper, were shown. Professor Tulletton proposed, and Mr. Mitchell seconded, a hearty vote of thanks to the lecturer for his instructive and stimulating address on a difficult subject which he had helped to make clear.

PUBLIC HEALTH IN AMERICA AND IRELAND

Dr. W. J. Russell, medical officer of health for the borough of Dublin, and Dr. R. P. McDonald of the Ministry of Local Government and Public Health (Irish Free State) to accept the invitation of the Rockefeller administration to study public health administration in the United States. They visited ten States and certain districts in Canada. One of their most vivid impressions was the enormous importance the Americans attached to public health. Not alone did the Federal State and the municipal authorities spend money unstintingly on this administration, but private citizens were so appreciative of its value that they all seemed prepared to contribute lavishly towards the funds of private societies interested in this matter. The Rockefeller Foundation alone was endowed with 180,000,000 dollars, which was devoted to education and research work in public health matters. Charitable societies were also generously endowed, and as evidence of the funds at their disposal Dr. Russell gave the figures of the relief afforded to one family which came under his notice. It consisted of husband, wife, and five children, ranging in age from 3 to 13 years. The husband, who was suffering from tuberculosis, was sent to a home, and his wife received the following relief: 28 dollars a month for rent, 49½ dollars for food, 6½ for fuel and light, 22½ for clothes, and 7½ for sundries. This allowance was made from a private society. Their average allowance in cases of distress was 19 dollars a month for a child under 16. Insurance companies were very large subscribers toward public health funds. The medical inspection of school children was most thorough and efficient. A great deal was also done in immunizing children against diphtheria and scarletina. American corporations were highly staffed in the professional and technical branches. The city of Toronto, with a population of 800,000, employed 23 doctors and 150 nurses in its public health administration. All the other cities both in Canada and the United States had large staffs of doctors and dentists in their employment, either as whole- or part-time officers, and these enjoyed the

co-operation of private societies. The milk question in the United States had been dealt with very drastically, and now 90 per cent of the milk sold was pasteurized, in some cases the average was as high as 98 per cent. In many States restaurants must have a licence and were rigidly supervised, and in nearly all persons handling food must have a clean bill of health. At one large dairy at Princeton, near New York, where some 1,000 cows were kept, every employee had to have a health certificate, all the cows were free from tuberculosis, they were examined regularly, as were the employees. In many places funds were contributed towards compensating dairy-keepers for the destruction of tuberculous cows. The housing question, as known in Ireland, did not exist in America here and there a little trouble arose over rents, but there was no scarcity of accommodation. Dr. Russell and Dr. McDonald found that each family had a flat, consisting of three rooms and a kitchen, with light, water, and other modern facilities supplied. It was common to see notices to the effect that spitting in tramways or underground or on overhead railways was a misdemeanour punishable by a fine of 500 dollars or twelve months' imprisonment with hard labour. The result of this was that that particular offence was practically unknown in America. Another right precaution was the refusal to allow any child that had not been vaccinated into the schools. In spite of all these advantages, Dr. Russell is strongly of opinion that Irish people are better off in their own country, from a health point of view, and he states emphatically that anyone who wishes to enjoy a long, healthy life would be well advised to remain at home in Ireland.

VITAL STATISTICS IN NORTHERN IRELAND

During the quarter ending September 30th, 1925, 7,124 births were registered in the twenty-seven superintendent registrars' districts of Northern Ireland, this number being equivalent to an annual birth rate of 22.2 per 1,000 of the estimated population. In England and Wales during this quarter the birth rate was 18.6 per 1,000, and in Scotland 20.8. The population of Northern Ireland is estimated at 1,281,000, including the military forces. The deaths in Northern Ireland during the same period numbered 3,858, representing an annual rate of 12 per 1,000. The death rate in England and Wales during this quarter was 9.7, and in Scotland 10.9. The death rate in Northern Ireland was 0.4 below the average rate for the third quarter of 1924, and 1.4 below the average rate for the third quarters of the years 1915-24. Of the total deaths registered 726, or 18.8 per cent, occurred in public institutions, and 407, or 10.5 per cent, were unclassified, there having been no medical attendant during the last illness and no inquest held.

India.

FREE OPHTHALMIC HOSPITAL, PAREL

THE Free Ophthalmic Hospital was founded at Parel, Bombay, in 1914, with the object of providing free treatment for the poor, and 1,284 patients were treated in the first twelve months. Starting with only six beds, the inpatient accommodation had to be doubled within the first year, and a few years later the number of beds was increased to eighteen. In 1922 a local supporter provided some urgently required new buildings in memory of his wife. The hospital report for the year 1924 illustrates the rapidity with which the activities of the hospital have increased the out-patient attendances, which in 1914 were 5,561, have risen to 25,707 in 1924. Accommodation has now been provided for paying patients, special rooms having been set aside for them. Post-graduate training in ophthalmology is now proceeding actively, and thirty clinical assistantships are available at the hospital. It is hoped to add soon a modern operating theatre in the place of the existing one, which is inadequate, and bacteriological and pathological laboratories are also contemplated. It is only possible at present to supply food

to destitute in-patients, the remainder having to provide their own. It is proposed to build a kitchen of adequate size for the preparation of food for all patients and under the direct control of the hospital staff. Nursing has hitherto been entrusted to ward boys, but three or four fully trained nurses will be engaged as soon as the financial conditions improve. The only regular grant received by the hospital is a yearly sum of 1,500 rupees from the municipality, and voluntary contributions are at present insufficient. The hospital is situated in an area of mills and workshops, with the result that over 1,200 cases of injuries due to foreign bodies were dealt with during the year. Errors of refraction accounted for 12 per cent of the new cases during 1924, and granulations and ectropion for 11 per cent each. More than half of the patients with granulations came from the provinces along the coastline. In treating phlyctenular conjunctivitis it was found that a certain number of cases refractory to the usual treatment were benefited by gradually increased doses of tuberculin. With griseofulvin the best results were obtained by trephining, with iridectomy.

HEALTH IN THE PUNJAB DURING 1924

In 1923 there was a moderate outbreak of plague in the Punjab during the spring months, it lingered on through the hot weather in an unusually large number of districts, with a recrudescence in the autumn. Circumstances were, therefore, very favourable for its extension at the beginning of 1924, and an epidemic of very grave dimensions followed. By the end of July 246,046 persons had died, and by the end of the year the mortality exceeded a quarter of a million, a figure surpassed in only three other years (1904, 1905, and 1907) since the first appearance of plague in the province in 1898. All districts were involved, Lahore and Rawalpindi being more severely infected than others, the disease was, as usual, more severe in the rural areas than in towns. The decline of the epidemic was, contrary to custom, less abrupt than the onset, owing to the unusual type of weather during April and May. The disease in most cases was of the bubonic type, but in almost every district an appreciable number of septicaemic cases was reported. Very energetic preventive measures were adopted, and we referred to these in our issue of December 13th, 1924 (p. 1135). Antiplague inoculations reached a very high figure, and many striking instances of its great value were forthcoming, despite the fact that the unprecedented demand for vaccine from all parts of the country was only met with great difficulty. Although in some cases the great value of preventing infected villages was manifest, yet in others evacuation was postponed until too late, and was incomplete. Little use was made of segregation camps and plague hospitals, but the great camp erected in the Minto Park at Lahore showed that evacuation even of large cities is not impossible. In his report on the public health administration of the Punjab for 1924 Lieut.-Colonel C. A. Gill insists that for the solution of the plague problem reliance must still be placed on intensive rat destruction during the quiescent period in potential plague centres, combined with inoculation and evacuation during the plague season. In the Dutch East Indies the problem has been solved by rehousing the population, but this method is not applicable in the Punjab, though Colonel Gill remarks that it is significant that no Europeans and very few Indians, living in houses designed on Western lines, contracted plague during the epidemic. He adds that even though rehousing is not possible it is clear that the plague problem would be much simplified if, on the first appearance of rat mortality, infected dwellings were immediately abandoned and their inhabitants accommodated in temporary quarters on the outskirts of the villages. Relapsing fever broke out in two districts during the year, but the mortality was not serious and the epidemics were quickly overcome. Cholera reappeared in epidemic form, and was responsible for over 4,000 cases and 3,000 deaths, as compared with 11 deaths in the previous year, but the spread of infection was soon checked by public health measures. The small-pox mortality during 1924 was 4,040, as compared with 2,140 during 1923, and an average annual mortality rate of 6,601 during the preceding five years.

Correspondence.

BLOOD TRANSFUSION IN CARBON MONOXIDE POISONING

Sir,—In the *BRITISH MEDICAL JOURNAL* of December 5th (p. 1049) Sir Charles Gordon-Watson gives a very interesting account of six cases (all of which recovered) of poisoning by fumes in a dug-out. The two worst cases were saved by transfusion next day, but I think that Sir Charles is mistaken in inferring that this fact indicates that transfusion in similar circumstances might be equally successful in cases of carbon monoxide poisoning.

It is probable that all the men were at first affected by carbon monoxide, but this affection cannot have been serious, as they were all able to escape by their own effort, and it was only later, at the clearing station, that the severe symptoms appeared. Sir Charles points out that some other agent than carbon monoxide may have been partly responsible for these later symptoms, but it seems to me that the chemical evidence, so clearly given, shows that this other agent must have been wholly responsible. The extraordinary dark colour which developed in the lips and skin, and the manner in which the symptoms increased in severity, are inconsistent with carbon monoxide poisoning. On the other hand, the absence of lung symptoms, and the fact that even the administration of pure oxygen caused no improvement of the dark colour, seem to exclude the theory that any lung irritant gas, such as phosgene or nitrous fumes, was responsible.

It seems clear that the symptoms were such as are produced by a poison which causes shortage of oxygen by converting oxyhaemoglobin into methaemoglobin or other decomposition product incapable of transporting oxygen from the lungs. Such substances as nitrites or dimethyl-benzol are known to produce symptoms exactly similar to those described, but on the data available we can only guess at the substance responsible. A guess which seems fairly probable is that nitrite originating from the ammonal of the Mills bombs which were exploded by the heat was suspended in the air of the dug-out. If this was the cause the blood would have, during life, the chocolate colour described, but would, after death, have assumed a more or less bright red colour, closely simulating that of acute CO poisoning, but actually due to the formation *post mortem* of NO haemoglobin, as was recently pointed out by Banham, Savage, and myself (*BRITISH MEDICAL JOURNAL*, August 1st 1925).

It seems to me that, while there was every indication for transfusion in the two cases described, there is none in cases of carbon monoxide poisoning which have not recovered rapidly. Carbon monoxide is eliminated fairly quickly from the blood, which is practically free of it after several hours, and the very severe symptoms which often remain are not due to existing shortage of oxygen, but are after-effects of shortage of oxygen when this has lasted for a considerable time. Neither transfusion nor administration of oxygen can be expected to have any good effect in such cases, though oxygen administration, particularly if about 5 per cent of carbon dioxide is added to the oxygen as recommended by Yundell Henderson, will greatly hasten the elimination of carbon monoxide, and so in many cases avert the after-effects if the exposure has not been too long—I am, etc.,

J S HALDINE

THE LEAD TREATMENT OF CANCER

Sir—Professor Adams, in his letter published in the *JOURNAL* of November 28th (p. 1034), states that "death and absorption of the cells of malignant growths can be brought about by an agent of known composition administered in known doses." He also states in a previous communication that cases of cancer have been cured for periods of three years or more, the natural assumption therefore, is that these agents of known composition have been in the hands of the Cancer Research Committee, Liverpool University for at least that period.

In October 1924, I wrote to Professor Blum Bell asking

if he could give me details of the methods which were being adopted for the treatment of cancer by lead under his direction, but he answered in a letter of October 17th that the preparation of lead which they were using had not been brought to the level of perfection which they hoped to achieve, he added that anyone who was unwilling to go to Liverpool to learn the methods, druggists, etc., at first hand they could not help. I at once wrote offering to visit the Research Department at any time convenient to Professor Blair Bell, but was then told that individuals could not be given the information, but only delegates from institutions.

From other sources I understand that the colloidal preparation of lead which is being used can be manufactured in London, and I therefore fail to understand why full details of the methods of treatment of these cases could not have been given to the profession long enough ago. There are admirable and efficient organizations in several towns in England, where the testing of any preparations for the treatment of cancer can be carried out, and it seems to me a very great pity that Professor Blair Bell has not seen fit to give the fullest information he has to the rest of the profession as soon as it was available.—I am, etc.,

London W 1, Dec 2nd

CECIL A. JOLL.

EDUCATION OF THE PUBLIC AS TO CANCER

SIR,—In the House of Commons last week, as reported in the *BRITISH MEDICAL JOURNAL* (November 28th, p 1036), the Minister of Health was asked a question regarding the advisability of instituting in this country a system of free clinics for cancer similar to that which has been in existence for some years in the United States. The free clinic is part of a wide scheme of cancer propaganda in the States, the results claimed for which are now so striking that the time is clearly ripe for a consideration of its value in Great Britain. In deciding on this question two facts are to be emphasized. In the first place, the very considerable chance of cure by surgery and radiation treatment in the early stage of cancer has within recent years been proved conclusively. This is especially obvious in accessible cancers. Thus the incidence of five-year cures after operation where the cancer has not spread to the glands is up to 90 to 95 per cent (Johns Hopkins Hospital, Mayo Clinic), breast 70 per cent (Johns Hopkins), tongue 62 per cent (Johns Hopkins), cervix 58 per cent (Bonner). With radiation treatment in cervical cancer the results are equally striking. Thus in early and border-line cases Heyman records 40.5 per cent five-year cures, and in early cases Doderlein's results are as high as 80 per cent. The next point to be emphasized is that the very considerable powers which we thus possess are largely frustrated by the fact that, even in the most accessible cancers (breast, breast, and uterus), the majority of cases are seen only at a late stage. When the causes underlying this lamentable fact are considered there can be no doubt that the most important is ignorance on the part of the public of the signs of early cancer, as also of its curability at the early stage. Few women know that a lump in the breast is dangerous, and that if sho is over 40 it implies cancer in an 80 per cent degree; few women know the danger that may underlie an irregular bleeding, especially when this occurs at 35 years of age or over, few men know the dangers of a non-healing sore of the lip or tongue, etc. Few people know that cancer in its beginnings and during its curable stage is rarely a painful ailment.

About 50,000 persons die annually from cancer in this country. Of this total, in about 15,000 to 18,000 the disease occurs in regions where early diagnosis allows of a proved curability into varying in different sites from about 60 to 95 per cent. After allowing for the cures actually accomplished by surgery and radiation treatment, Childs has computed that in males at least one-third, and in females at least one-half, of all cancers are capable of early removal and cure. This means, under ideal conditions, a potential annual saving of about 7,000 male lives and 13,000 female lives, or a total potential annual saving of about 20,000 lives. This is a goal to be reached in very ideal circumstances, but even if only realizable in a 50 per cent degree it is obviously worthy of the most strenuous endeavour.

A little reflection will show that the only way to reach the thousands of cases of early cancer is by education of the public. The problem is largely outwith the province or power of ordinary medical practice. It is a problem essentially of community health and community instruction. This great fact has been recognized by our American colleagues and by American publicists earlier than by ourselves, and for many years this recognition has found expression in the activities of such bodies as the American Society for the Control of Cancer. The most useful of these activities, it is claimed, is the popular lecture. There is, in addition, propaganda carried out through the lay press. In connexion with "Cancer Week" there are free clinics where people with suspicious lumps, sores, etc., can find advice. At Detroit, for example, during four days 1,100 persons applied to eight hospitals, and in this number 42 cancers were discovered (face 7, lip 4, breast 16, uterus 8, etc.), and 75 pre-cancerous lesions. In Idaho, in seven small communities, 108 cases of early cancer were so discovered. At seven clinics during Cancer Week in Pennsylvania 886 patients were examined. Of these 146 had pre-cancerous conditions requiring treatment, 40 had early and 19 had late cancer. The success of this propaganda is seen also in the fact that patients are coming earlier to the routine hospital clinic. Thus Bloodgood (professor of surgery at Johns Hopkins Hospital) says that in this regard the results are almost incredible. At his clinic in the decade 1890-1900, of the breast cases 99 per cent required operation and 85 per cent were cancerous, whereas lately only 50 per cent required operation, and of these only 50 per cent were cancerous. At the same clinic the operable tongue cases have increased from 53 to 80 per cent. Pimrose (professor of clinical surgery, Toronto University) states that at his clinic within the past decade 37.5 per cent of the breast cancers came to operation within three months of the initial symptoms, as compared with 19 per cent in the previous decade, 27 per cent came within one month, as compared with 8.4 per cent in the former decade.

An organized crusade against cancer has the further advantage of providing a channel by which all that is known regarding prevention can be conveyed to the public, and new facts can be utilized quickly as they transpire. Within its operations there will be embraced all medical agencies in contact with the public, such as public health authorities, midwifery and other nurses, health visitors, etc. The Minister of Health, in Circular 426 dated as far back as 1923, has already officially recognized that education of the public is essential to a successful attack on the basic problem, and I know from inquiry that some local health authorities in this country are alive to the advantages and possibilities of a well planned scheme. But before such bodies can exert their full powers they must have behind them the support of organized and articulate medical opinion. I have shown that the crusade in America has proved by results the efficacy of such a movement. It may be that the intensive press and platform methods adopted there would be unsuited to this country, and that other schemes of permeation would be better here. It is clear that caution is necessary in the means employed, for unwise methods and overstatement can do much harm by creating panic and unfounded hopes. On the other hand, it may be considered certain that a wisely planned effort would result in the saving of many lives. To the student of community health it is known that the argument of panic was advanced against the antituberculosis crusade at its inception but all now recognize that in this disease the results following publicity, backed by adequate provision for diagnosis and treatment, rapidly swept away this natural dread of panic and at the same time the sentiments of loathing which tuberculosis was wont to inspire in the public mind.—I am, etc.,

Edinburgh Nov 28th

NASAL PLASTIC REPAIR BY CARTILAGE GRAFT

SIR,—While sincerely congratulating Mr E Watson-Williams on his cartilage graft results (November 28th, p 987) we are sorry that Mr J F O'Malley (December 5th, p 1091) confirms and approves the method of approach

In a series of several hundred cartilage grafts we have naturally tried this incision, and gave it up because of the scar on the tip of the nose. It is, of course, a great improvement on the incision at the root of the nose which we also practised and abandoned early, but we do not think it is justifiable to make any scar on the outside of the nose if the operation can be done without.

In certain cases the whole operation of planting cartilage in the nose can be done through the vestibule, but in others it is wise to use the incision shown before the Royal Society of Medicine in 1923 (*Proceedings*, vol. xvi, Section of Laryngology, pp. 4-6), which leaves a scar only across the root of the columella.

We have persistently maintained that the correct operation is the introduction of an "L-shaped" piece of cartilage, and we do not think this can be inserted through the incision described by Mr. Watson-Williams.—We are, etc.,

London W. 1, Dec. 7th

ABDOMINAL CRISES IN CHILDREN

SIR,—In Mr. Adams's very complete survey of the abdominal crises in children (*BRITISH MEDICAL JOURNAL*, December 5th) there is a sentence (p. 1044) which might, I think, be modified. In discussing diagnosis with special reference to intussusception, he writes "Severe diarrhoea and dysentery are associated with bloody stools containing mucus, but some faecal matter is usually present."

In most cases of acute bacillary dysentery, soon after onset, the stool consists entirely of blood and mucus. Such dysenteric cases can be diagnosed from intussusception by rectal examination. In dysentery rectal examination sets up a degree of tenesmus which is manifest when, on attempting to withdraw the finger, it is somewhat forcibly expelled, and its expulsion is followed by a small quantity of blood and mucus, circumstances which do not occur in intussusception.—I am, etc.,

ROBERT RICHARDS, M.D., F.R.C.S. Ed.

Aberdeen Dec. 5th

TREATMENT OF PRIMARY ACUTE INTESTINAL OBSTRUCTION

SIR,—The paper on acute intestinal obstruction, by Sir William Taylor, at the Bath Annual Meeting (reported in the *JOURNAL* of November 28th, p. 993), will undoubtedly cause very great interest, as stated in your leading article.

It seems a pity that Sir William thought fit to open his remarks by a diatribe against a section of the profession whose difficulties he apparently fails entirely to appreciate.

I have no doubt whatever that everyone, even every general practitioner, will agree that the ideal to be attained is an early diagnosis, the great difficulty, I am afraid, is to make that diagnosis. In the books are given certain very definite and classical signs and symptoms of this condition, not one of which need be present in an early case, and which, in my experience, are generally absent. If they are present, then it is, as Sir William points out, very often too late.

Several other speakers, particularly Mr. Sampson Handley, pointed this out, and some mentioned the value, as an early sign, of complete constipation. If this were easy to be sure of, it would be very helpful, but very often one is met by a statement that constipation for one and often more days is a regular habit of the patient, in such cases as these it is very hard to estimate the importance of that part of the history. In a case which I mention later the patient had definite diarrhoea.

The value of enemata also is variable. In three out of four cases I have seen recently an enema produced excellent results, no doubt owing to the large bowel being fully loaded and the obstruction being higher up. Such results from an enema only help to increase the difficulty of diagnosis and make the anxiety of the general practitioner still greater.

The books tell us that tenderness and rigidity are often

absent in the early stages. This is perfectly true, but not very helpful, it merely increases anxiety in a doubtful case.

Pain and vomiting vary so much as to be most puzzling. I have seen a case in which there was no vomiting at all, and at the operation several feet of small gut were found to be strangulated by a band. In general practice one is called to dozens of cases a year of acute abdominal pain, the great majority of these turn out to be nothing at all serious, thereby increasing our difficulty in deciding which is the serious case and which is not.

My experience of the condition under discussion is not vast, but I have yet to see a case in which, in the early stages, the pulse and temperature were anything but normal, so that these usually valuable signs do not help us here.

As a general practitioner I may say that no other illness or condition seems to present the same difficulties and pitfalls in diagnosis as this acute intestinal obstruction, and yet we are told by Sir William Taylor that we are deserving of a civil action for damages if we fail to make an early decision. May I give as an example one of the most tragic cases I have had?

A thoroughly healthy and strong man of 50 had a good breakfast on Saturday morning. Soon afterwards he had pain in the abdomen and back and vomited his breakfast. He went to work and felt quite all right, having his bowels open during the day and no more vomiting. On Sunday he had a loose action of the bowels three times, and so kept to a light diet, he did not vomit again. On Monday morning he did not feel very well, so stayed in bed and sent for me. I found him with an "ache" in his back, normal pulse and temperature, moist furred tongue, abdomen quite flaccid, no tenderness or distension. I ordered an enema and very light fluid food. I saw him again in the evening, and his condition was exactly the same and he felt quite easy, he had not vomited nor had he had any more pain. The enema had produced a moderate result. I proposed calling the next morning but at 5 a.m. I was called and found him dead, he had gone to sleep as usual but had suddenly awakened, vomited some brown fluid, and died. *Post mortem* examination showed a complete obstruction of the small gut, high up, by a band.

I think this case should speak for itself in illustrating the difficulties of a general practitioner with this condition. I suggest that Sir William Taylor would help towards the attainment of his ideal more efficiently if he would write a paper giving us his friendly help and advice as to the early diagnosis of these cases. I can assure him that general practitioners would do their very best to turn that advice to good uses. His abuse affects us not at all, his help would be greatly appreciated and carefully used.

I am sure that we all felt grateful to these other surgeons who spoke, and who tried to assist and not to criticize.—I am, etc.,

Sheerne's Nov. 29th.

W. HOPPER SHEPARD,

POST-GRADUATE MEDICAL EDUCATION IN ENGLAND

SIR,—Sir Holburt Waring's address on post-graduate medical education published in your issue of November 28th is on the whole a very fair summary of the position of post-graduate education to-day. Sir Holburt has, however, done *him* justice to the Fellowship of Medicine, which, with all its faults, is doing something for the post-graduate.

I welcome his criticisms because they are not merely destructive, although all his remedies have been considered over and over again by the executive of the Fellowship, and have had to be deferred owing to lack of funds. I estimate that the outlay involved by his suggestions would amount to a capital sum of £400,000 and an annual maintenance of £50,000. We have an income of less than £3,000.

We should all like palatial offices, a medical director, and a hospital, but we cannot afford them at the moment. We all agree that post-graduates and undergraduates cannot be taught together, and it is arguable whether this is the fault of the post-graduate or of the teacher. It is possible that the undergraduate teacher, absorbed in his

important task of training beginners to pass examinations, has never acquired nor needed the wide outlook which is necessary to instruct men experienced in the difficulties of practice. And was that not one of the causes of the early failure of the Fellowship of Medicine? The question is referred to in the current (December) number of the *Post-Graduate Journal* by an overzealous correspondent.

Sir Holburt Waring must be patient. It is only two and a half years since the Fellowship of Medicine was reorganized and control placed in the hands of the actual teachers. In this short time the Fellowship of Medicine has affiliated some fifty hospitals in London, has arranged general and special classes covering the whole range of medicine and surgery, with a programme arranged for twelve months' work, has started a journal of its own, and is embarking on an extensive scheme to attract overseas students. There is a steady increase in the number of post-graduates on the books and there is a modest balance in the bank.

Sir Holburt Waring's criticism that the Fellowship of Medicine is not incorporated by Royal Charter or by registration would be sound were it not that the memorandum and articles of association of the Fellowship of Medicine have been drawn up and will be signed in a few weeks—I am, etc.,

London W 1 Dec. 7th

H W CARSON.

Sir,—I have read Sir Holburt Waring's address (*BRITISH MEDICAL JOURNAL*, November 28th, p. 1022) with interest, and am in agreement with much of it. Sir Holburt does not, in my opinion, quite strike at the root of the trouble. Post-graduates fall naturally under one of two categories: (1) Those who are able to devote their whole time temporarily to post-graduate study; (2) Those engaged in practice or holding public appointments who have only a strictly limited time at their disposal.

The former class is fairly well provided for under present arrangements, the latter may take advantage of the yearly ticket issued by the West London Post-Graduate College, but the cost of tickets issued by many of the other hospitals is prohibitive. If several of the better known hospitals would set aside one or two days a week for post-graduates, and issue a yearly ticket at a nominal charge, I am sure the latter class would take full advantage of the arrangements.

Again, one cannot fail to notice that many hospitals arrange revision courses for those taking the F.R.C.S., but no such arrangements appear to exist for the M.R.C.P. candidate, surely this should be remedied—I am, etc.,

November 29th

M D

OSTEOPATHY AND CHIROPRACTIC

Sir,—An "osteopathic aurist" (so described in the telephone directory) treated for slight deafness a middle-aged patient for whom I was called up by telephone at 11 p.m. recently. After ascertaining that he was no longer under the osteopath's care, I went and found the patient ill in bed with a temperature of 103.9, right tonsil enlarged, tender gland beneath jaw, and intense redness of both external auditory meatuses at upper parts near the drums, especially the left. The previous day, under gas, the osteopathic aurist had manipulated the nasopharynx about the Eustachian orifices.

Incidentally he was induced under pressure to undergo Plombières treatment (rectal irrigation), to which he weakly acceded, though he felt doubtful of its efficacy in his case.

The temperature became normal in five days, and after a week in bed the patient was well enough to go home. A week later he wrote that he was not yet quite as fit and strong as usual.

While in bed he showed me a letter written by mother of this osteopath's patients, who wrote that after her operation she too had fever and had to lie up some days before she was well again.

My patient was fortunate in escaping acute middle-ear suppuration—I am, etc.,

London W 1, Dec. 2nd.

BERNARD E. POTTER

THE PREVENTION OF COLD IN THE HEAD

Sir,—May I be allowed to supplement the excellent paper by Dr. Simey on the prophylaxis of common colds (*BRITISH MEDICAL JOURNAL*, November 14th, p. 901) by some remarks which the lateness of the hour prevented me from adding to the long discussion that followed it?

My attention was first directed to this subject many years ago, when first I made the acquaintance of a middle-aged gentleman and his wife, neither of whom had ever suffered from a cold in the head, and who, though they carried pocket-handkerchiefs—chiefly for dusting purposes—had never had to employ them for "blowing the nose."

The lady was of Irish parentage, her husband was a member of one of the numerous branches of a well-known family which occupies prominent positions throughout several counties from the Northern Midlands to the southern coast. For nearly half a century I have been intimately acquainted with more than fifty of its members of both sexes and have from time to time met and observed several others. They are a prolific race (a fact of some significance), and the men all present the following characteristics: a well-formed face, with broad jaws, affording ample room for well-developed evenly spaced teeth, and a sonorous voice of pleasing quality. All of them can tell the same story of never suffering from cold in the head and of not needing to use a handkerchief. Their health has been robust—with the single exception of one on whose mother's side there was a marked family history of tuberculosis, he died comparatively early and of a comparatively trivial malady.

I have been able to examine fifteen of these exceptionally gifted persons with great care and more than once, in health and in illness, and several others with less thoroughness, and what impressed me in each case was the absolutely perfect formation of the oro-nasal cavities: there was no spur, no deflected septum, no exaggerated or ill-formed turbinate, there was every facility for a complete and even flow of the normal nasal moisture (it could scarcely be described as a "fluid") along the smooth and even slopes provided. There were no ridges or irregularities to form pools in which the mucus could accumulate and become infected by organisms under conditions which would favour their development into active and irritant toxicity. Some of them were very heavy pipe-smokers, they showed chronic congestion of the fauces and tonsils in varying degrees, from which they did not suffer conscious inconvenience. In all, the maxillary sinuses were well and symmetrically developed. I was able to observe some of them during attacks of influenza. The malady followed a normal course, but was never attended by any running from the nose or any interference with the sense of smell. I examined several of the women with equally good results, though as a rule the good points in their case were less complete and less evenly distributed.

I have been driven to the conclusion that the perfect and symmetrical development of the oro-nasal cavities reveals the secret of this unusual freedom from the nasal troubles which are nowadays practically universal throughout the British Isles, and common enough elsewhere. For it will be admitted that nearly all of us have "colds" from time to time, and that very few of us possess perfect nares. Such embarrassing and displeasing conditions are quite unnatural. They are the inevitable result (1) of a deliberate thwarting of the natural and beneficent instincts of early infant life, (2) of the foolish and injurious habits impressed upon the child in the later stages of its existence, (3) the fostering of these habits by example.

Before any tooth has emerged from its gums the infant, left to itself, instinctively puts any hard substance which it can grasp into its mouth and bites upon it. The pressure thus made upon the swollen gum above the tooth beneath it achieves the discomfort which the child feels—much as an adult may often find that biting on an aching tooth lessens the pain by emptying the gorged blood vessels and numbing the super-sensitive nerve endings. The infant's "biting" is not a simple vertical "clump", it is of a grinding character, the lower jaw being moved slightly from side to side. It

Community Settlements we look to those in the Dominions far-sighted enough to realize their potentialities. We do not propose to have any financial interest in the enterprise, or in fact any interests at all, save the interests of those for whom the scheme is designed.

Through private channels and by the valuable aid of the principal Government departments and service banks, details of our project have been circulated in many quarters. The response was immediate and enthusiastic, so much so that Sir Roland Bourne, our vice chairman and the originator of the project, is now in South Africa examining offers from responsible interests there to furnish the facilities needed for the first Community Settlement. He has cabled and written that suitable offers are assured.

Our present need is to make known the provisions of our scheme to all those to whom it might be of interest, and perhaps benefit. To this end, will you allow me, through your columns, to invite those interested to write for further particulars to the Empire Community Settlement Committee's head office at 89, Kingsway, London, W C 2?—I am, etc.,

NEO CARDIOLOGY

SIR,—Dr Harrington Sainsbury (November 28th, p 1031), in adversely criticizing the methods of investigation of neo-cardiology, finds fault rather with the conclusions drawn than with the apparatus employed. He is voicing, I think, an attitude which is very general. Personally, I have frequently opposed the explanations offered of the records made.

Take, for instance, the wave *a* in the jugular curve. Sir James Mackenzie, in the second edition of his *Diseases of the Heart*, wrote "The forces operative in producing variations in the auricular pressure are also acting in producing the jugular pulse. Both are due to the systole of the auricle." This gratuitous assertion I opposed in a short article on the genesis of the venous pulse in the BRITISH MEDICAL JOURNAL of April 13th, 1912. It is a terrible condemnation of the efficiency of the human heart to assert that the auricle works also backwards into the jugular whenever it attempts to drive blood forwards into the ventricle. If for its explanation the wave *a* requires such an assumption, it is a pity that the wave *a* was ever recorded.

The study of the phases of the heart's action by the polygraph and electro-cardiograph gave considerable promise of usefulness, because they introduced accurate physical methods. Unfortunately the polygraph, being very indirect in its application, has produced curves which the investigators have found very difficult to explain, and others more difficult to follow.

The electro-cardiograph records only the electrical changes originating in the heart, which, fortunately, may be some measure or indication of the strength and duration of the cardiac contractions, consequently they are of more than mere laboratory interest. Its application, however, is limited, and can seldom serve as a key to cardiac problems.

The riddle of graphic records has turned cardiologists aside from the clinical problems of the previous generation, which, though less showy, seemed far more profitable. Is it not time we again took some interest in the evidence of our ears as well as our eyes? Take, for instance, the presystolic murmur heard near the apex. Who discusses it now? And yet does it not tell us that the mitral orifice is constricted, that the auricle is contracting vigorously to drive the blood through it, that the prolongation of the murmur up to and into ventricular-systolic time indicates that the murmur manages somehow to keep up its contraction into ventricular-systolic time, and force its blood into the ventricle, even after the latter has commenced its contraction? Even the electro-cardiogram shows that the auricular contraction may be simultaneously prolonged, and physical principles indicate that the auricle late in its contraction should be more than a match for the full ventricle. Does not the cessation of the presystolic murmur coincide with the break down of compensation, and with the occurrence of a systolic regurgitant

murmur? Then it is that the murmur dilates probably for the first time, for if a sufficient be killed by accident dilatation is generally absent, though commonly present with the hypertrophy after natural death. This I proved statistically in my article, "Mitral stenosis: a statistical inquiry," in the BRITISH MEDICAL JOURNAL of February 5th, 1898.

After all the elaborate methods lately introduced for investigating the heart's action, the one practical conclusion which has emerged is that the heart's condition should be judged, not by these curves, but by its "response to effort." It cannot be so judged any more than an old motor car can. Its parts, its sounds, and its general condition must be examined in detail, for "a short life and a merry one" may easily go together—I am, etc.,

Menton, France, Dec. 3rd

D W SAINSBURY

SIR,—To adopt the new is not to discard the old, and I think I can comfort Dr Sainsbury and Dr Thorne Thorne with the assurance that those of us who are familiar with graphic methods are yet not ignorant of physical signs and the "palaeo-cardiological" methods of examination. These latter methods in many cases of heart disease or supposed heart disease suffice and will continue to be adequate, whatever new aids the profession is endowed with in the future.

We have in the polygraph and the electro-cardiograph instruments which enable us to analyse with precision all abnormalities of rhythm, but most of us through time require the knack of recognizing clinically the various irregularities with more or less certainty, and I shall not stress this point. What I would emphasize with all the force I can is that by clinical examination we may learn nothing of the myocardium. Pace Dr Thorne Thorne, the unfortunate owner of a degenerated myocardium may yet possess normal heart sounds, normal heart borders, and normal blood pressures, but he will not yield a normal electro-cardiogram. I had thought the fallacies of percussion and auscultation in myocardial disease too notorious to require comment.

No one would assert that we have yet reached finality in the investigation of heart disease, but it is certain that in the electro-cardiogram we obtain a record whereby we detect disease of which clinically we were ignorant, and whereby we confirm disease of which clinically we were but suspicious. By these records examination achieves precision, prognosis and treatment acquire decision, positive clinical findings are revealed as facts, and negative clinical findings are in many instances revealed to have the value which negative evidence possesses in other parts of the body, in others they are confirmed, and then the patient and his medical attendant may go on their way rejoicing, for the electro-cardiogram will not let them down—I am, etc.,

Hove Dec 7th

DAVID HALL

PREHISTORIC TREPHINING

SIR,—I have a photograph of the Dutch oil painting "Senox" refers to (BRITISH MEDICAL JOURNAL, December 5th, p 1090) concerning other reasons for trephining in ancient times besides depressed fracture. It was painted by Jan Steen, Rotterdam. My copy was given me by the late Mr Arthur F G Leveson Gower, who was prompted to inquire concerning such pictures by seeing an old Dutch print which I possess by Weydmans, which represents the same operation, this latter has an old Dutch legend beneath it which Mr Leveson Gower referred to the curator of the museum (I think) where the painting by Jan Steen is, and he forwarded the following translation "I go, I go, with great joy, here they will operate on the woman of Ayo (Kyen, Keien) for stones in the head," and added the footnote, "A fictive operation, stones in the head = stupidity."

There is also another painting by Jan Steen, of which I gave me a copy, entitled "The Quack Doctor," which represents the same operation being performed, apparently by an itinerant quack, who is holding up for exhibition to the surrounding bucolics the stone which he professes to have removed from his patient—I am, etc.

London E 1 Dec 5th.

LARRY SIMMONS

Obituary

SIR JOHN MACALISTER,

Late Secretary of the Royal Society of Medicine

WE had the grief last week to record the death, on the evening of December 1st, of Sir John MacAlister, the first secretary of the Royal Society of Medicine. He had been in failing health for about a year and had been compelled on this ground to resign last April.

John Young Walker MacAlister was born at Perth in 1856, the second son of Donald MacAlister, of the ancient family who were keepers of Tarbert Castle. His elder brother is Sir Donald MacAlister, Bt, Principal of Glasgow University and President of the General Medical Council. John MacAlister was educated at the High School, Liverpool, and studied medicine for three years at the University of Edinburgh. Owing to ill health he had to give up his purpose of entering the medical profession, and in 1878 became sub-librarian of the Liverpool Library. In 1880 he was appointed librarian of the Leeds Library, where the new buildings were erected in conformity with his recommendations. He classified the collection of some 50,000 volumes, and was also concerned in the planning and arrangement of the Yorkshire College. He had already done some journalistic work in Liverpool, and now became a contributor to the *Liverpool Mercury* and *Yorkshire Post*. In 1887, on the recommendation of Professor Thorold Rogers and Mr Herbert (now Viscount) Gladstone, he was nominated librarian of the newly founded Gladstone Library at the National Liberal Club, London, but had only held the post for a few months when he was elected, on August 9th, 1887, resident librarian of the Royal Medical and Chirurgical Society, then in Berners Street, in succession to the late Mr J B Baile, who had been appointed librarian of the Royal College of Surgeons of England. MacAlister continued to take a practical interest in librarianship, and in 1889 founded *The Library*, a periodical devoted to technical work of librarians and to the literature of libraries, it was at first published monthly, but afterwards became a quarterly, in the conduct of which MacAlister was associated with Professor A W Pollard, it is now the organ of the Bibliographical Society. In 1887 MacAlister became honorary secretary of the Libraries Association, and was largely concerned in the passage of the Public Libraries Act of 1892, under which public libraries are now conducted. He helped in obtaining the Royal Charter of Incorporation for the Libraries Association in 1898, and in that year ceased to be its secretary. He remained an active member, and from 1914 to 1919 was its president. When the second International Library Conference was held in London in 1897 he was its secretary general.

MacAlister's chief life work, however, was done for the Royal Society of Medicine, which is the direct successor of

the Royal Medical and Chirurgical Society, founded in 1805 by the then leaders of the profession in London. Their conception of it was a society comprehending the several branches of the medical profession for the purpose of conversation on professional subjects, for the reception of communications, and for the formation of a library. This society prospered, and in 1835 bought the lease of 55, Berners Street, where its work was carried on when MacAlister became librarian. It had a fine library and a well proportioned meeting room, but was outgrowing its accommodation, moreover, the lease had nearly expired. MacAlister proposed that the society should get a larger house, and found for it No 20, Henrietta Square, which was first occupied, after it had been renovated and largely reconstructed, in 1890. The society continued to prosper, and celebrated its centenary there in 1905. Meanwhile, however, a large number of specialist medical societies had

been founded in London, and there was a widespread feeling that this led to a waste of effort. The matter was first brought to a head by a scheme MacAlister submitted in 1893 to Sir Andrew Clark, then president of the Royal Medical and Chirurgical Society, who was warmly in favour of amalgamation, but he died suddenly on the day on which he had convened the first meeting, and the proposal lapsed. In 1905 it was revived by a scheme submitted by MacAlister to Sir Richard Douglas Powell, then president of the society, who heartily approved it. At his house a number of meetings were held, as is mentioned in the short appreciation from him appended to this notice. Eventually he proposed that representatives of all medical societies in London should be invited to attend a meeting at the Royal College of Physicians, at which the President of the College, Sir William Church, was in the chair, an Organizing Committee was formed with Sir William Church as chairman, and Mr Pendlebury and the late Dr Arthur Latham as honorary secretaries. The

SIR JOHN MACALISTER
(After the portrait by Eric Kennington)

committee carried on negotiations with the several societies for nearly two years, until in June, 1907, the supplemental charter was granted by King Edward VII, and fourteen medical societies joined the Royal Medical and Chirurgical Society and became the Royal Society of Medicine. After this the prosperity of the society increased rapidly, and in 1910 the site now occupied at the corner of Wimpole Street and Henrietta Street was required. In May, 1912, the new house was formally opened by the King who was accompanied by the Queen. It provides a meeting hall dedicated to Dr Robert Brines, several smaller meeting rooms, and a fine reading room, in which a collection of books is placed, the remainder being housed in the capacious storerooms in the basement.

MacAlister was associated with Sir St Clair Thomson in founding the Inter-Allied Fellowship of Medicine, which had for its object the encouragement of co-ordination in medicine among the nations and especially the care of the social needs of foreigners and our fellow countrymen of

the Dominions when in London. After the armistice the Dominions Governments gave their medical officers a period of study leave before demobilization. To meet the need thus created the Fellowship undertook the establishment of post-graduate courses in London. The effort was successful and for many months the courses were well attended, and it will be remembered that the British Medical Association held a special General Clinical Meeting at the Imperial College of Science in April, 1919, which also was largely attended. In the autumn the Fellowship amalgamated with the London Post-Graduate Association, but after the period of study leave for overseas officers had ended the numbers attending the courses naturally fell off. MacAlister, however, continued to work with enthusiasm for the establishment of a good practical plan of post-graduate instruction, and it is largely through the success of his efforts in keeping the organization alive that we have now come to the point when the Minister of Health has appointed a committee under his own chairmanship to advise as to the means that can be taken to establish a first-rate post-graduate medical college in London.

A funeral service at St. Peter's, Vere Street, was held on Saturday, December 5th, when the large congregation was composed almost entirely of representatives of the medical profession. The King was represented by Sir Edward Wallington, and among the immediate family mourners, beside the widow and her two sons, was Sir Donald MacAlister. The President of the Royal Society of Medicine, Sir St. Clair Thomson, was accompanied by four past presidents—Sir William Church, Sir Henry Morris, Sir Humphry Rolleston, and Sir William Hale-White. Other officers of the society included Mr. Walter Spence (honorary librarian), Mr. C. H. Fagge (honorary treasurer), and Mr. W. Gilling Ball and Dr. H. Letheby Tidy (honorary secretaries). Representatives were also present from kindred societies and medical institutions. The British Medical Association was represented by the Treasurer, Mr. N. Bishop Harman, and the *British Medical Journal* by the Assistant Editor, Dr. N. G. Horner. The congregation included also Sir Dyce Duckworth, Sir George M'Kins, Major-General Sir W. G. Macpherson, Sir Hector MacKenzie, Sir Chilton Biscoe, Sir George Blacker, Sir Hugh Rigby, Sir James and Lady Dundas Grant, Sir James and Lady Berry, Professor G. Elliot Smith, Dr. A. M. H. Gray, and Mr. Geoffrey R. Edwards. The staff of the headquarters of the Royal Society of Medicine attended.

Sir St. Clair Thomson, President of the Royal Society of Medicine, has sent us the following tribute:

By the death of Sir John Y. W. MacAlister we have lost one of our best friends. It is doubtful if any man, not himself a graduate in medicine, has ever done more for the profession than the late secretary of the Royal Society of Medicine. His good work was commenced thirty-eight years ago, when he started as librarian to the Royal Medical and Chirurgical Society. At that date, although the leading body of its kind in London, this society numbered only 745, and was housed in three dark little rooms in Beiers Street. When, a few months ago, Sir John retired owing to ill health, he had effected an astonishing change in the academic life of the profession in the metropolis.

It was chiefly through his organizing talents that the Royal Medical and Chirurgical Society moved to a larger house in Hanover Square, and there amalgamated itself with eighteen other distinct medical societies of London into the now flourishing Royal Society of Medicine. Sir John's indomitable energy was the chief factor in erecting the handsome home for this great amalgamation at the corner of Wimpole Street and Henrietta Street. He who had commenced as librarian to a society of 745 Fellows, with an income of about £1,600 per annum, lived long enough to be secretary of a society of 4,000 Fellows, with an income of £20,000 a year, and possessing, among other valuables, the largest medical library in the British Empire.

This fusion of eighteen separate and independent societies was really a Herculean work, if it is remembered how many conflicting interests and jealousies had to be

overcome. Many efforts at the task had failed since the foundation of the original Royal Medical and Chirurgical Society in 1805. It was nearly successful in the time of Sir Andrew Clark, but the untimely death of that great physician arrested progress until amalgamation was finally accomplished in the year 1907, when Sir William Church, ex-President of the Royal College of Physicians, became the first President of the Royal Society of Medicine. This great achievement was doubtless accomplished because MacAlister was a man with imagination, was absolutely devoid of selfishness, and was single-hearted in his devotion to a great idea. Fortunately he was a man endowed with a serene and equable temperament which allowed his Celtic imagination to be controlled by the more rational spirit of his Southern friends. If any project of his was occasionally turned down as visionary or impracticable he was neither resentful nor cross about it.

His handsome presence will not easily be forgotten. He was twice threatened with tubercle. He suffered from other troubles, for the relief of which he was ever grateful to his old friend Sir Arbuthnot Lane. But he never looked the invalid. Broad shouldered and erect, with his handsome head of hair and curling beard, with the refined straight nose and the high cheek bones of the Celt, his one grey and his other blue eye added an increased charm, while his clear diction and low musical voice had an attractive and caressing effect. In his prime there was something about him suggestive of the Viking type, with which much of the Highland strain on the coast of Scotland is mingled. This same Celtic strain gave him a love of hospitality, a sociability, a courtesy, a facility of approach, and a pliability which is sometimes wanting in the Lowlander. Possibly it also accounted for a certain respect for the ceremonial and *bravura* of public affairs, and for the simplicity and frugality of his private life.

He was known to and beloved by successive generations of medical men. There is hardly a consultant or specialist in London to whom he was not a friend and a helper. Outside the profession he was ready to join in any undertaking of public interest, and particularly those concerned with books and libraries. His catholic tastes were shown by his membership of the Athenaeum, Garrick, and Bath Clubs, and his life membership of the Savoy Club. He was, in Dr. Johnson's true meaning of the word, "a very clubbable man."

The council intends to hang his portrait, a photograph of which is here reproduced, in the entrance hall. Fellows will recognize in this fine picture that the artist has not omitted to indicate, by the surroundings, his love of books and libraries, and his great share in the erection of the society's house. The cigar in his hand indicates his devotion to "my lady nicotine," and no sweeter incense could be burnt before his picture than the tobacco smoke which will in future curl up round it during the tea hour.

It is one of the curious, though not uncommon, coincidences of our great country that MacAlister and the last president to be associated with him both came from small neighbouring villages on the shores of Loch Fyne, and yet it was not in Argyllshire but in Berners Street that they met for the first time.

When I saw him shortly before he died he told me he had not smoked for two days, and then, as Mistress Quigley said, "I knew there was but one way." He was able still to take great interest in the most recent doings of the society, and gave one to his well known chuckle when I told him that the annual dinner had been so managed that it had left us with a profit instead of the usual deficit. He had neither distress nor pain, for the devoted attentions of his family, his friends, and his faithful attendant, Dr. Moreland McCrea, had smoothed the last passage. His only complaint and his last words were, "I am only tired—very tired—always tired."

His best and most enduring memorial will be the house or the society he served so long and faithfully. As was said of Sir Christopher Wren: "Si monumentum requiris circumspecte." If those interested care to look up *Who's Who* they will see that he has quizzingly recorded that his chief recreation was "sleeping." After life's fitful fever our friend sleeps well.

Sir HUMPHRY ROLLSTON, Bart, FRCP, who was President of the Royal Society of Medicine from 1918 to 1920, has been good enough to send us the following

On John MacAlister's death, after a long and tiring period of increasing disability, removes a personality remarkable for chain of manner, infinite variety, and organizing ability. He had, indeed, a genius for friendship, and was characterized by the impulsive enthusiasm of a generous boyish nature to help others. A many-sided man, he had friends everywhere and of the most varied kinds, with an univalued knowledge of men and their manners there was no touch of cynicism or imprudence, and though from his sympathetic nature secretly sensitive he preserved a philosophic imperturbability in spite of constant ill health and many worries. Had not his career as a medical student been cut short by illness, he must have been an outstanding success in our profession, as indeed he would have been in other walks of life. While a brilliant raconteur he was pre-eminently a man of action and imagination, risks he certainly sometimes took, but always with the happiest results for the Royal Medical and Chirurgical Society, and later for the Royal Society of Medicine, which was his child and is his memorial. What he did for the Royal Society of Medicine is shown by a comparison of the old society in Beine's Street and its 800 Fellows with the flourishing society now at Wimpole Street with its twenty-four sections and its roll of some 4,000 Fellows. Careless of his own interests and much given to generous hospitality, he did much better for others than for himself, but his reward was in the hearts of his friends, who feel that no one can ever quite take his place.

Sir WILLIAM HALF-WHITE, who was president of the Royal Society of Medicine from 1922 to 1924, writes

On John MacAlister was, nominally, not a member of our profession yet, in truth, no man was ever more a part of it. How did he come to occupy this unique position? Primarily because he loved the medical profession. He had intended to belong to it when he went to Beine's Street he hoped that the proximity of the Middlesex Hospital would give him the opportunity of studying there. But he quickly came to see that his unusual combination of natural gifts could serve the profession in better ways than by becoming a doctor.

The gods had endowed him with their best, he had imagination, he dreamed great dreams, he had the power of organization and of incredible industry, no obstacle ever daunted him, he delighted in a difficult task for the sheer joy of accomplishing it. Never did he play for his own hand, he invariably strove for the cause, but always honourably. He was as unselfish as anyone could be, he gave unstintingly of the most valuable of all commodities—his time—working for others far into the night, on Sundays and on holidays. Many came to him to talk, wasting his precious moments with trifles, he never turned them away. He was kind and considerate because it was not in him to be otherwise. Nobody ever heard of anyone who did not like working with him, doing so had the remarkable result that toil became a pleasure, the eye ceased to wander towards the clock in the hope that the hands were pointing to the hour for stopping and overtime was positively delectable. He was generous in his appreciation of others, he had a keen sense of humour, and, as might be expected, he knew everybody and had troops of friends. He was happiest when with them, how enjoyable it was to sit and talk with him! But he knew fools, too, he combined an affection for good writing with the librarian's delight in a rare edition.

He utilized these priceless qualities for the good of others without any thought of self, he was constant in the doing of true and laudable service with a great cheerfulness. Little wonder that hosts of persons felt a deep and lasting affection for such a man, and that he was a fountain from which spring many plans for the benefit of the profession to which he had happily attached himself.

That I have not overestimated him will be clear to those who read his life, the account of the Royal Society of Medicine given in its calendar, and the report of the dinner given to him when he received his knighthood. But even then the extent of what he did will not be fully known, for he collected a large sum of money for the building at

1, Wimpole Street, he started the library in its course, in which it has become the second finest medical library in the world, and, what is more important, the most used, he edited the *Proceedings* out of mere goodness of heart without pay, he promoted the Fellowship of Medicine and was its honorary treasurer, he organized a staff of surgeons for air-raid casualties—indeed, he was in thought and action perpetually working solely for our profession. Whenever anything needed doing for it, he was the man to whom to apply—his enthusiasm, his energy, and his resourcefulness combined to be an almost irresistible driving force. The motto "*Si monumentum requiris circumspice*"—put up by Wien over the north door of St Paul's—might with equal justice have been inscribed by MacAlister over the entrance to the Royal Society of Medicine, and if his friends had to choose a motto for him the one word "Service" would be the best.

Sir RICHARD DOUGLAS POWELL, Bt, writes in response to our request

I held in high esteem Sir John MacAlister for his width of vision, his subtlety of mind, and tenacity of purpose. He was a great librarian, and earned on the good work of the late Mr Whentley in the development of the society's library to its present perfection. But the work for which he will be remembered is that of bringing about the amalgamation of the various medical societies in London under one roof. This idea was already in the air when I became president of the Royal Medical and Chirurgical Society, and had been started during the presidency of Sir Andrew Clark, but I am not sure whether he originated it. It fell through at that time, and was again started by MacAlister about my second year. I most cordially approved and did all I could, by meetings and social gatherings at my house, to promote it. But without MacAlister's clever organization and zealous work it would never have materialized. The details were largely in the hands of a strong committee, with Sir William Church as chairman, and Mr Pendlebury and the late Dr Litham as honorary secretaries. I am very pleased to think that the scheme has proved a complete success and the societies have become harmoniously welded together, while retaining their autonomy to the honour of medicine in this country. This has largely been accomplished under Sir John's fostering care and by his devoted loyalty.

Dr GUSTAVE MONOD, who is so well known here as liaison officer between the Paris Faculty and medicine in this country, sends us the following

Les amis Français de Sir John MacAlister (et tous ceux de nous qui avons franchi le seuil de cette belle maison dont il était l'âme sommes devenus ses amis) ressentiront douloureusement sa perte. Il savait particulièrement faire vibrer cette note spéciale qui harmonise l'esprit Ecossais et l'esprit Français et possédait ce don congénial de nous faire sentir à home. Gracia à lui l'P.A.D.R.M. était devenu comme un poste avancé à la Faculté de Médecine de Paris du Fellowship of Medicine et le souvenir de reconnaissance que nous lui gardons ne saurait s'éteindre.

Votre deuil est le nôtre

RICHARD DENISON PEDLEY, FRCS Ed, L.D.S.,
Consulting Dental Surgeon Evelina Hospital

Mr R. D. PEDLEY died on November 25th at his home in Croydon, aged 68. He was the eldest surviving son of the late George Pedley, who practised for many years as a dental surgeon at Railway Approach, London Bridge. After studying at St Thomas's Hospital and the Royal Dental Hospital he obtained the diplomas of M.R.C.S. Eng. in 1883, L.D.S. in 1884, and F.R.C.S. Ed. in 1887. He then entered his father's practice, and worked with him until his death. For many years he held the post of dental surgeon to the Evelina Hospital for Sick Children. At this period of his life he took the greatest interest in the problem of the care of children's teeth, writing freely on the subject and doing much of the pioneer work which eventually led up to the general appointment of school dentists to elementary schools throughout the country. He was one of the first presidents of the School Dentists'

Society, and when this society became a group of the Society of Medical Officers of Health he was chosen as its representative on the council, thus taking an active interest in its work until the time of his death. He was also a member of the council of the London and Counties Medical Protection Society, and was a regular attendant at its meetings. His kindly and lovable disposition and sincerity of character endeared him to hosts of friends.

SIR ARTHUR NEWSHOLME writes: The announcement of Mr Denison Pedley's death after a short illness—he saw ten patients on one day within a fortnight of his death—will have been received by his many friends with profound regret. Mr Pedley had a genius for friendship, he cultivated his many friends, and although always a very busy man devoted time to keeping in touch with them. Professionally Mr Pedley deserves to be held in memory as a pioneer in the subject of dental hygiene in this country. To him and to his co-workers we owe it that appointments of dental surgeons to many Poor Law residential schools were made at a comparatively early date after the dangers of oral sepsis had become recognized. In conjunction with Mr Spokes, dental surgeon of University College Hospital, Mr Pedley, who was then on the staff of the Evelina Hospital, with the permission of the respective boards of guardians, examined the children maintained in the Poor Law schools of Southall, Harefield, Sutton, and Feltham. In these schools 3,800 children's mouths were examined during 1891-92, and exact records taken, with the general result that over 78 per cent of the teeth examined were found to be carious, the proportion varying with the age of the children. When the facts became known to the guardians there followed the appointment of dental surgeons, and since then such appointments have become general, similar appointments have been made for elementary day schools, and a vast amount of remedial and preventive work has been done, which has had great influence in raising the standard of health of the population. Much of this work done by dental surgeons in various parts of the country, especially in the earlier years, is but little known, and Mr Pedley's death gives the opportunity of bearing testimony to the invaluable pioneer public health reforms which were stimulated and expedited by his work and by that of those associated with him in bringing about dental reform.

We regret to record the sudden death on November 28th, at his residence, Goring Hall, near Worthing, of Dr JOHN ELSDALE MOLSON, formerly a medical member of Parliament. He was born in 1863, the son of Samuel Elsdale Molson of Montpelier, From Cheltenham College he went to Emmanuel College, Cambridge, and afterwards studied medicine at the Middlesex Hospital Medical School. He obtained the diplomas of L.S.A. in 1889 and M.R.C.S. and L.R.C.P. in 1890, graduated M.B., B.Ch. Cantab. in 1891 and proceeded M.D. in 1905. He contested North-East Bethnal Green at the two parliamentary elections in 1910, and from 1918 to 1923 represented, as a Unionist, the Gainsborough Division of Lincoln in the House of Commons. He held a commission as major R.A.M.C. (T.A.), and served at home and in Egypt during the great war from August, 1914, to December, 1918. He was a justice of the peace for West Sussex. His chief recreations were shooting, motoring, and golf. He is survived by his widow, a daughter of the late Dr A. E. Leeson, three sons, and a daughter. The funeral took place at St Mary's Church, Goring-by-Sea, on December 2nd.

In the obituary notice of Lieut Colonel Decimus Curme, published last week (p. 1095), an error occurred owing to a confusion between him and his son, Lieut Colonel Duncan E. Curme R.A.M.C. It was this Regular officer who served in South Africa, and not his father, who, during the South African war, served with the 3rd Battalion (Militia) of the Dorsetshire Regiment at Kinsale and Shorncliffe camp. We are informed also that the day on which Lieut Colonel Decimus Curme died was November 24th.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE House of Commons this week passed through all its stages the bill implementing the new Irish agreement. It also completed consideration of the resolutions proposing import duties on cutlery and other articles, and discussed the bill giving effect to these resolutions. The second reading of the Bethlem Hospital Bill was moved once more on December 8th, but objection was again taken, and the measure now seems to have no chance of passing into law this session.

It is anticipated that the session of 1926 will begin on February 3rd, and that the bill for reform of the Poor Law system will have a prominent place in the programme.

The Government has withdrawn the Lead Paint (Protection against Poisoning) Bill.

The Medical Committee of the House of Commons met on December 7th and heard members of the General Medical Council (Professor T. Sinclair, C.B., M.P., of Belfast, and Sir Humphry Rolleston, Bt.) and the Registrar of the Council detail the procedure of that body in considering charges of "infamous conduct in a professional respect." The presence of a legal assessor at sittings of the Council was emphasized, and attention was drawn to the fact that a case could be taken to the Privy Council, though this had scarcely ever been done. One speaker remarked that the barrister, solicitor, or dentist who was struck off the register was debarred from practising his profession, whereas no such penalty was imposed on the medical man whose name had been removed from the Register. There was a keen debate in the Committee, which eventually adjourned the discussion till Wednesday, December 16th, when the policy, as well as administration, of the General Medical Council may be considered. It can be said that the general opinion of the Medical Committee was that the system as it exists is administered fairly and efficiently by the Council.

The General Medical Council and the "Medical Register"

Colonel Woodcock, on December 3rd, asked the Minister of Health whether his attention had been called to the recent action of the General Medical Council in striking off the *Medical Register* one of its members for what was described as "infamous conduct in a professional respect," whether the Minister was aware that the General Medical Council was now composed wholly of medical members and whether, seeing that the statute did not require that the General Medical Council should be composed exclusively of medical men, he would, in nominating members of the Council, take steps to add members representing the public.

Mr Neville Chamberlain said: The answer to the first and second questions is in the affirmative except that the practitioner to whom I understand my hon. and gallant friend to refer was not a member of the General Medical Council. The answer to the third question is that members of the Council other than those representing certain bodies specified in the Acts are nominated by His Majesty with the advice of his Privy Council. The Minister departmentally responsible is the Lord President of the Council.

Colonel Woodcock: Is the right hon. gentleman aware that there is no appeal whatever against the punishment inflicted by the Council and will he therefore, set up a committee to investigate the procedure of the Council and its relation to modern usages and methods? Mr Lawson: Is it not worth while taking steps to make the Trade Disputes Act apply to these people?

Mr Chamberlain: I think the answer to the first supplementary question is that I am not the Minister departmentally responsible.

Sir W. de Frece: May we ask who is the Minister responsible? Mr Chamberlain: I have already said in my answer that it is the Lord President of the Council, Commander Kenworthy. Who represents the Lord President of the Council in this House?

Sir Robert Gower then asked the Minister of Health whether his attention had been called to the action of the General Medical Council in removing the name of Mr William Lloyd from the Register of medical practitioners for having given treatment to certain patients and whether he would consider the necessity of introducing legislation restricting the power of the General Medical Council to strike off the *Medical Register* the names of practitioners who had not been proved to be guilty of actual misconduct and giving him power to replace on such Register the name of any person which, in his opinion, had been capriciously or

Mr Chamberlain said: I have consulted my noble friend the Lord President of the Council (the Earl of Balfour) on this matter as responsibility rests with him and not with me. The name of Mr William Lloyd was not, as I understand it, removed from the *Medical Register* by the General Medical Council for having given treatment to certain patients, but for having sought to obtain patients and promote his own professional advantage by unprofessional methods. I am furnishing my hon. friend with a copy of the charge on which Mr Lloyd was summoned to appear before the Council. In answer to the second and third parts of the question, I am advised that the General Medical Council has

statutory power to direct the erasure from the *Medical Register* of the name of a practitioner who has been convicted in England or Ireland of any felony or misdemeanour or in Scotland of any crime or offence or has after due inquiry by the Council been judged to have been guilty of infamous conduct in a professional respect. I am further advised that there is no evidence that the Council has directed the erasure of the name of any practitioner without his having been thus convicted or thus judged after due inquiry to have been guilty of infamous conduct in a professional respect as defined by Lord Justice Lopes, Lord Justice Dyer and Lord Esher. In regard to restoration it has been the practice of the Council to replace names on the *Medical Register* when it is satisfied that such a course will not be prejudicial to the public interest. My noble friend has no reason to believe that the Council has acted capriciously or unreasonably, and as at present advised does not consider that the introduction of further legislation is necessary, there being already power under the relevant Acts for the Privy Council to issue its directions to make good any defaults in practice of the General Medical Council.

Colonel Watts Morgan: Are we to understand from that reply that this is a penalty inflicted on Mr. William Lloyd for having acted as a blackleg to his trade union? Commander Kenworthy: Do we understand that questions which come within the purview of the Lord President of the Council are answered in this House by the Minister of Health and if not to whom should we address questions affecting the public which can only be answered on behalf of the Lord President of the Council?

The Speaker promised to look into this question, which Commander Kenworthy said he would raise again.

In reply to Colonel Woodcock, who on December 8th asked the Prime Minister whether members struck off the *Medical Register* had no redress or appeal and whether a committee would be appointed to investigate the procedure of the Council, Major Hennessy (Lord of the Treasury) replied: I am asked by the President of the Council to say that there is no appeal from the General Medical Council to another court, but a medical practitioner struck off the *Register* may at any future session bring up his case for revision and his name may be and often is, restored to the *Register*. In all inquiries the General Medical Council is assisted by a lawyer of great experience and ability. It has since its creation in 1858 performed the duties entrusted to it without serious criticism and the Lord President, as at present advised, does not think that sufficient reason has been shown for setting up a committee of inquiry. Colonel Woodcock asked whether members of the Bar, solicitors and members of all professions except the medical profession had an independent court of appeal. Professor Sinclair (Belfast) asked whether it was not a fact that practitioners struck off the *Register* had a right of appeal to the Privy Council if they cared to exercise it. Major Hennessy said that Colonel Woodcock's observations would be conveyed to the Lord President.

Inquiry Committees and Panel Practitioners' Costs.—On December 3rd Lieutenant Commander Kenworthy asked the Minister of Health the total number of committees of inquiry convened, since these committees had power to award costs, for the purpose of inquiring into a practitioner's fitness to remain on the panel; the number of cases in which the practitioner was unsuccessful in rebutting the suggestion that he was unfit to remain on the panel; and the amount of costs awarded to the practitioner in each case. Mr. Neville Chamberlain replied that since the Inquiry Committee referred to had had power to award costs thirty-four inquiries had been held. In twelve cases the inquiry resulted in the practitioner being removed from the medical list and in one case he was permitted to resign in lieu of removal. In five of these thirteen cases no order was made as to costs. In fifteen of the remaining cases the facts disclosed were held to justify requiring the practitioner to pay the costs of the imposition of other penalties. In three cases no order was made and in three cases costs were awarded to the practitioner; the respective amounts being £35 3s 4d, £59 4s 2d, and £4 4s.

Ministry of Pensions.—Replying to questions regarding tuberculosis among ex-service men, Major Tryon (Ministry of Pensions) said the total number of ex-service men who had received awards from the Pensions Ministry was not on record. He regretted to say that during the ten years down to November 30th about 21,000 men pensioned for tuberculosis had died of the disease. Approximately 33,500 men were now in receipt of pensions for tuberculosis pulmonary or other. He could not say in how many unsuccessful applications for a pension on account of tuberculosis the men concerned were diagnosed as having suffered from the malady before entering the army. The weight of medical evidence required to refute applicants' claim that they did not suffer from tuberculosis before entering the army depended on the circumstances in each case. In reply to Mr. Groves, Major Tryon said that on November 1st 26,148 pensioners were receiving medical treatment with allowances. Only twelve men remained in training courses completing a course of vocational training with treatment. He could not say how many pensioners were receiving home treatment without allowances. The general rule was that men applying for treatment were referred to the Deputy Commissioner of Medical Services in the area to be examined or referred to the most suitable medical officer. In cases of urgency the man might be sent to the nearest clinic or medical officer for immediate examination without prior examination by the D.C.M.S. Answering Colonel Day, Major Tryon said he was satisfied there was no ground whatever for removing from the Ministry of Pensions Hospital at Orpington the medical officer recently summoned by a patient for assault. Colonel Day further asked whether in view

of general complaints the Minister would consider making a complete change in the staff of this hospital. Major Tryon said that practically the entire medical staff had been changed on medical grounds when the hospital was adapted for the class of patient now sent there. Lieut. Colonel Stanley, on December 8th, informed Captain Bower that a procedure was already in operation which met the cases of wounded ex-service men whose wounds broke out and caused trouble after their time limit for appeal had expired. In such cases not only was the disabled man eligible for medical or surgical treatment with allowances if necessary, but his assessment for pension purposes was considered at the conclusion of treatment and any necessary adjustment of it as was proper was made by way of further grant. He could not recommend that appeal tribunals should adjudicate on these cases on their merits, which would render nugatory the provisions of Section 4 of the War Pensions Act 1921.

Air Force Hospitals.—On December 4th Brigadier General Charteris asked the Secretary for Air what was the present number of equipped beds in hospitals under the Air Ministry, and the average daily number of patients in these hospitals during the current year. Sir S. Hoare said that the answer to the first part of the question was 1,586 to the second 528. Of the 1,586 equipped beds 1,139 were in hospitals in Iraq and Palestine which catered for the whole garrisons—that is Army as well as Air Force and British as well as Indian troops and in Palestine the British gendarmerie in addition. It was necessary to provide beds considerably in excess of the average occupation in order to be in a position to cope with epidemics, casualties, seasonal illnesses and the special conditions under which the forces in the Middle East were serving, but their number would continue to be brought under constant review. A further answer stated that the medical staff at Halton Hospital consisted of nine officers and ninety-four airmen but their duties were not confined to providing medical attendance for the Halton School, the hospital being a central one for the whole Air Force.

The Cost of Vaccination.—In response to an inquiry by Mr. Groves the Minister of Health has given the following information as to the cost of vaccination and revaccination and the charge upon national and local funds respectively:

England and Wales

Year	Number of Successful Vaccinations and Revaccinations Performed by Public Vaccinators at the Cost of the Rates		Approximate Expenditure Incurred in Respect of Public Vaccination	
	Vaccinations	Revaccinations	Expenditure out of Local Rates	Expenditure out of Exchequer Funds
1914-1915	—	—	£ 144,000	£ 25,000
1915-1916	—	—	138,000	12,000
1916-1917	—	—	129,000	16,000
1917-1918	199,013	33,635	116,000	21,000
1918-1919	186,861	16,052	110,000	20,000
1919-1920	258,996	12,893	124,000	18,000
1920-1921	245,154	26,775	175,000	15,000
1921-1922	223,838	12,887	162,000	22,000
1922-1923	415,549	316,611	181,000	20,000
1923-1924	331,522	89,600	—	—

The figures in columns 2 and 3 relate to the years ended September 30th those for the years 1914 to 1917 are not available. The figures in columns 4 and 5 relate in each case to the year ended March 31st those for 1923-24 are not yet available.

Tuberculosis Deaths.—On November 26th in reply to Mr. Groves who asked the number of persons who died in England and Wales from tuberculosis during the years 1914 to 1924, Mr. Neville Chamberlain gave the following figures:

Deaths from Tuberculosis (all forms) in England and Wales		Deaths from Tuberculosis (all forms) in England and Wales	
Year		Year	
1914	50,298	1920	42,545
1915	54,295	1921	42,678
1916	53,858	1922	42,777
1917	55,934	1923	40,788
1918	58,073	1924	41,103
1919	46,312	Total	528,661

Neurological Clinics.—On December 7th Captain Waterhouse asked the Minister of Pensions what general instructions if any had been issued to officials with a view to cutting down the number of patients receiving treatment in neurotic clinics. Lieut. Colonel Stanley, who replied, said that the general instructions in force were issued with the object of securing that all patients who required it received appropriate and efficient treatment. The operation of the neurological clinics was under the general supervision of the Deputy Commissioner of Medical Services for neurological cases who was a specialist and was responsible for seeing that the treatment carried out at the various clinics was both necessary and satisfactory.

Medical Welfare of Young Children.—Mr. Neville Chamberlain, in reply to a question on December 3rd said it was untrue that no provision existed for the medical welfare of children between 2 and 5 years of age. The arrangements made under the Maternity and Child Welfare Act did not exclude any category of children under school age and the Ministry of Health lost no opportunity of impressing upon the local authorities in charge of maternity

and child welfare schemes the importance of maintaining a continuous supervision over children up to the age at which they attended school.

Army Hospitals—On December 4th, answering Brigadier General Charters, Sir L. Worthington Evans said that in military hospitals under the control of the War Office the number of equipped beds at home and abroad on October 31st 1925, was 6,751, and the average daily number occupied during the year ended on that date was 3,567. On December 8th Captain King informed Sir W. de Frece that the number of men invalided from the army in each of the last three years ending on September 30th had been 2,920, 2,673 and 2,673 respectively.

The number of cases in which disability service were 373, 419 and 347 respectively. The decision of appeal against the decision of the Chelker Commissioners were an independent body who adjudicated upon the soldier's claim and were not subject to the control of any Government department in administering the pension regulations.

Artificial Sunlight—On December 8th Mr Neville Chamberlain stated that he was advised that artificial sunlight treatment was still in the experimental stage, but he had approved of the provision of such treatment under skilled supervision, for children suffering from rickets and other disorders of infancy and childhood, at a certain number of infant welfare centres, in order to secure further evidence as to the results of the treatment.

Small pox—On December 8th Sir Kingsley Wood informed Mr Groves that the only death from small pox registered in Middlesex during the quarter ended June 30th, 1925 was in respect of a child aged one month. The cause of death given in the medical certificate was 'Bronchopneumonia following small pox,' and in accordance with the general rules based upon international agreement the death was classified as being due to small pox. The child had not been successfully vaccinated. Sir J. Gilmour (Secretary for Scotland), on December 8th informed Mr Westwood that the Registrar General for Scotland had not classified the deaths from small pox in Scotland for the years 1870 to 1875 into vaccinated unvaccinated, and doubtful. Such classification was not introduced in the Registrar General's reports until a later period.

Notes in Brief

Of 39 fatal accidents in the Royal Air Force since the beginning of the year causing 55 deaths 3 were due to engine failure 19 to error of judgement, 1 to constructional defect, and 16 to miscellaneous or undetermined causes.

On October 21st there were 1,270,186 persons in England and Wales in receipt of Poor Law relief excluding lunatics, casuals, and persons in receipt only of domestic medical relief. Mr Neville Chamberlain informed Mr. Phys that the amount expended in England and Wales on administrative charges in respect of the relief of the poor during the financial year ended March 31st, 1924, was £1,187,906.

In the four weeks of November 1923, the deaths in London from pulmonary diseases were 1,207 in the similar four weeks of 1924, 1,064 and from November 1st to 28th 1925, 1,190. In the last period there were 344 deaths from tuberculosis of the respiratory system, 320 from bronchitis, 321 from bronchopneumonia, 94 from lobar pneumonia, and 53 from pneumonia (undistinguished).

The Home Secretary stated on December 3rd, that in July he referred to the Mining Association and the Miners' Federation, for their observations proposals for amending the present descriptions in the schedule of industrial diseases for miners' bent knee and miner's bent elbow. Neither body had so far furnished him with its views.

The Minister of Agriculture states that the available evidence indicates that infection of foot and mouth disease is generally spread by means of mechanical carriers, which may be either human beings or other living agencies, or by contaminated food stuffs, hay or straw.

In reply to an inquiry as to the establishment of dental consultation centres for insured persons Mr Neville Chamberlain said that before considering any extension of the benefits provided he must await the report of the Royal Commission.

The Services

THE KING has granted licence and authority to Lieut. General Sir William B. Leishman K.C.B., K.C.M.G., F.R.S., Director-General of Army Medical Services to wear the insignia of Grand Officer of the Legion of Honour conferred upon him by the President of the French Republic in recognition of valuable services rendered.

NO 14 STATIONARY HOSPITAL

The annual dinner of the No 14 Stationary Hospital was held at the Trocadero Restaurant London on December 4th. Lieut. Colonel J. R. Harper C.B.E., in the chair, proposed the toast of the hospital to which several informal toasts were made in the shape of reminiscences. It is proposed to hold the next dinner on the first or second Friday in December, 1926.

Universities and Colleges

UNIVERSITY OF OXFORD

The reappointment of Dr. Alexander G. Gibson (Christ Church) as University Lecturer in Morbid Anatomy has been approved by Convocation.

UNIVERSITY OF CAMBRIDGE

THE Special Board for Medicine has appointed Professor G. H. F. Nuttall F.R.S., Dr. W. J. Dixon, F.R.S. (Reader in Pharmacology), Mr. D. Keith Dr. Frank Robinson (M.O.H. Cambridgeshire County Council), and Dr. A. J. Laird (M.O.H. Borough of Cambridge) as members of the managing committee for the Diploma in Public Health.

UNIVERSITY OF LONDON

A MEETING of the Senate was held on November 18th. The following were recognized as teachers of the University in the subjects and at the institutions indicated.

Westminster Hospital Medical School—Mr. Aubrey Goodwin (midwifery and diseases of women).

St. George's Hospital Medical School—Mr. George A. Fawcett (surgery).
London Hospital Medical College—Dr. James C. Woods (mental diseases), Mr. G. H. Cutts (dental surgery).

biochemistry)
A. Maass as a
1 for two years.

The recognition of the Royal Dental Hospital and London School of Dental Surgery as a school of the University in the Faculty of Medicine (dentistry only) was continued for a period of three years from January 1926.

The annual report of the Graham Legacy Committee, giving particulars of general progress of the laboratory, the researches carried out, and the amount of the grants made to workers, was received. Professor A. E. Boycott F.R.S., was reappointed director of the laboratory.

The following have been appointed chairmen of the respective committees for 1925-26—**Brown Animal Sanatory Institution Committee** Sir Holburt J. Waring, **Graham Legacy Committee** and **Library Committee** Sir Wilmot P. Heringham.

UNIVERSITY OF EDINBURGH

THE following candidates have been approved at the examination indicated.

FR. — — — — — Elizabeth Cairns, I. J. W. Edwards, N. Hay, J. Hays, Latham, Mitchell, A. R.

UNIVERSITY OF DUBLIN

Regius Chair of Medicine

DR. T. GILLMAN MOORHEAD, F.R.C.P.I., Professor of Materia Medica in the University, has been elected Regius Professor of Medicine, in succession to Dr. John M. Purser, resigned.

NATIONAL UNIVERSITY OF IRELAND

A MEETING of the Senate was held on December 4th. Dr. D. J. O'Connell was appointed Lecturer in Medical Jurisprudence at University College Cork and the award of the Henry Hutchinson Stewart scholarship in mental diseases to Dr. William J. Coyne was approved.

A report from the Vice-Chancellor of the University, Dr. Denis J. Coffey, as representative of the University on the General Medical Council, was approved.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

THE following have been admitted to the Licences in Medicine and Midwifery.

H. I. — — — — — Brodenck, J. J. M. Barry, Mary F. L. D. Nolan, D. O'Brien, J. F. Scales, Mabel M.

M. J. Hillery, L.R.C.P. and S.I., has passed the examination for the Diploma in Public Health.

Medical News.

At the last meeting of the Joint Council of the Order of St John of Jerusalem and the British Red Cross Society, the resignation of Dr F N Kay Menzies as Director of the Jonnells Hospital and Medical Services Department, in consequence of his appointment as medical officer of health for the County of London, was accepted as from December 31st next. At the same meeting, Mr R H P Orde, B A, was appointed Acting Director of the Hospital and Medical Services Department as from January 1st, 1926.

EARLY in the new year various special courses will be held under the auspices of the Fellowship of Medicine and Post-Graduate Medical Association. A fortnight's course in medicine, surgery, and the specialties at the Prince of Wales's General Hospital (North East London Post Graduate College) will begin on January 11th. On January 4th the Bethlem Royal Hospital will start a series of lecture demonstrations on Tuesdays and Thursdays at 11 a.m. on the various branches of psychological medicine, the course lasting for four weeks. On the same date the West End Hospital for Nervous Diseases will begin a month's course in neurology, lectures and clinical demonstrations will be given daily at 5 p.m. The North Eastern Fever Hospital will hold a three weeks' course in infectious fevers, beginning on January 11th, the demonstration taking place at 11 a.m. on Wednesdays and Saturdays. A cardiology course will be given at the National Hospital for Diseases of the Heart from January 11th to 22nd. On January 18th the Queen's Hospital for Children will start a fortnight's course in diseases of children. The first of a new series of lectures arranged by the Fellowship of Medicine will be given on January 21st at 5 p.m., when Dr Herbert Spencer will lecture on "Abdominal palpations in pregnancy." A copy of each syllabus and of the general course programme may be had from the Secretary of the Fellowship, 1, Wimpole Street, W 1.

A FURTHER series of lectures and practical courses of instruction for a diploma in psychological medicine will be given at the Maudsley Hospital, Denmark Hill, S E 5, in the new year. Part I of the course comprises eight lectures on the anatomy of the nervous system, by Sir Frederick Mott, on Tuesdays at 2.30 p.m., commencing on January 5th, eight lectures on the physiology of the nervous system, by Dr F Golla, on Fridays at 2.30 p.m., commencing on January 8th, eight lectures on psychology, by Dr Henry Devine, on Thursdays at 2.30 p.m., commencing on January 7th. Part II, which follows in April, includes eight lectures on psychoneuroses, by Dr Bernard Hart, eight lectures on morbid psychology, by Dr E Mapother, six lectures on the pathology of mental diseases, including hysteria, syphilis, its symptomatology and treatment, by Sir Frederick Mott, lectures on the legal relationship of insanity and treatment, by Dr C Hubert Boud, eight lectures on the practical aspect of mental deficiency, by Dr F C Shrubbsall, six lectures on crime and insanity, by Dr W C Sullivan, six demonstrations in clinical psychiatry, by Dr E Mapother, and twelve clinical demonstrations in neurology, by Sir Frederick Mott. The fee for the whole course, Parts I and II, is 15 guineas, for Part I or Part II, 10 guineas, for one single series of lectures in Part I, 4 guineas, and for one single series of lectures in Part II, 2 guineas.

A MEETING of the members of the Institute of Radiology will be held at 32, Welbeck Street, on December 17th, at 3 p.m., the council meets the same day at 6 p.m. On December 18th, at 2.30 p.m., Dr Melville will give a special demonstration for members of the Institute at the Brompton Hospital for Diseases of the Chest, including the bronchial injection of lipiodol. At the meeting of the Lectro Medical Section of the Royal Society of Medicine on December 18th, at 8.30 p.m., discussions will be held on Paget's disease of bone, and methods of examination of the pelvic caecum.

THE Central Midwives Board for England and Wales met on December 3rd, with Sir Francis Champneys, Bt, in the chair. A special session was held in the morning, followed by the ordinary monthly meeting. A message of condolence was sent to the family of the late Mrs Brian Wilson, who had for many years been an active member of the Board. Dr C G Lewis was approved as lecturer, and approval as teacher was granted to several applicants. The resignation of Dr Fletcher Shaw as an examiner at the Manchester-Liverpool centre was received and the best thanks of the Board were accorded him for his efficient services. Mr John Chisholm, F R C S, was appointed to fill the post in Dr Shaw's stead. An application from the Midwives Institute to the trustees of the Carnegie Fund to contribute to a scheme for the establishment of an institute for the instruction of teachers of practical midwifery was signed by the chairman on behalf of the Board in its support.

MR C J S THOMPSON, M B E, has resigned his post as curator of the Wellcome Historical Medical Museum, with which he has been associated since its foundation.

THE house of the Royal Society of Medicine will be closed from Thursday, December 24th, to Monday, December 28th, both dates included.

THE November issue of *Asculape*, the official organ of the International Society of the History of Medicine, is devoted to the recent congress held at Geneva (reported in our issue of August 1st, p. 226), and contains numerous interesting portraits and other illustrations.

THE Municipal Council of Paris has decided to organize two centres for the preparation of serum from measles convalescents for prophylactic purposes, one to be at the Hôpital Claude Bernard at Aubervilliers and the other at the Hôpital des Enfants Malades in the Rue de Sevres.

THE first number of *Terapia Contemporanea*, which, as its subtitle indicates, is an international review of treatment, was published in October at Naples under the editorship of Senator G. Pascale of Naples and Professor G. Klempner of Berlin. The issue contains original articles by Italian, Austrian, German, Swedish, Danish, and Russian writers on medicine, surgery, ophthalmology, gynaecology, and orthopaedics, society intelligence, abstracts from current literature, and reviews.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are **MUSEUM 9361 9362, 9363, and 9364** (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are

EDITOR of the British Medical Journal, Antiology Westcent, London

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) **Articulate Westcent London**

MEDICAL SECRETARY **Madisena Westcent London**

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams **Bacillus Dublin**, telephone 4737 Dublin) and of the Scottish Office 6 Drumsheugh Gardens, Edinburgh (telegrams **Associate, Edinburgh**, telephone 4361 Central).

QUERIES AND ANSWERS

"H C D" about three years ago had charge of a patient who was treated by the Erlangen deep x-rays for a myoma of the uterus. The treatment was successful but for some months past she has been rapidly increasing in weight. "H C D" asks for suggestions as to what line of treatment he should now follow.

UTERINE PROLAPSE AND PREGNANCY

"J G B" asks for advice to ensure the birth of a living child in the presence of uterine prolapse. His patient aged 33 is three months pregnant. Her first child lived seven weeks and died from what may have been birth injuries as labour was long and much force was used during delivery. Her second child was born dead after a seven months pregnancy during the early part of which there was some uterine prolapse. Her third pregnancy resulted in the birth of a dead premature infant of about seven months after a breech presentation. A small ring pessary which had been placed in the vagina shortly after the commencement of pregnancy was simultaneously expelled. During her present pregnancy she has noticed that the womb has dropped and this renders walking uncomfortable. The vaginal orifice is somewhat patulous and the cervix is nearly presenting there. No other abnormality has been detected and syphilis can be excluded apparently. Would a pessary be useful until the uterus has risen out of the pelvis, or is prolonged rest necessary?

AIR SPACE IN A BEDROOM

"VIGILANS" writes to ask whether the local sanitary authority would have any jurisdiction over the proprietress of a boarding-house in regard to the letting, as a bedroom, of a box room

(approximately 5 ft by 6 ft) with no fireplace or window, the only ventilation being through a casement window opening on the stairhead

* * We are advised that if the room in question has come into use as a bedroom since 1894 this is a contravention of the London Building Act. If, on the other hand, it has been in use since prior to that date it is probably justifiable to assume that a room 5 ft by 6 ft, and probably less than 10 ft high, making less than 300 cubic feet in all, is unsuitable for use as a bedroom. The minimum cubic space required per person for sleeping for common lodging house purposes is 300 cubic feet. Furthermore, the model by laws of the Ministry of Health relating to habitable rooms require that at least one window shall open directly into the open air and that such window shall be equal to not less than one tenth of the floor area and that at least one half of the window shall be made to open. Ventilation through a casement window on to a staircase is not ventilation into the open air as required by this by law. The distinguished medical officer of health to whom we referred this question adds that, in his opinion, the room as described is unsatisfactory for sleeping purposes, and if such a case came to his notice he would be prepared to recommend the authority either (1) to take action under the London Building Act, if such Act applies, (2) to take action under the by laws based on the model by laws of the Ministry of Health, having regard to the improper character of the lighting and ventilation, or (3) to take action under the ordinary Nuisance Section of the Public Health (London) Act, 1891, as a house or part of a house so overcrowded as to be injurious to health.

BAGGY EYELIDS

DR T STACEY WILSON (Birmingham) writes: When baggy eyelids are due to blockage of the lymphatic channels by an attack of erysipelas I have seen very good results from the adoption of the following simple device, and doubtless the same treatment would cause the absorption of redundant fat in this situation. The following apparatus is required: Two deflated toy balloons of small size with six or seven inches of rubber tubing attached to each for their distension, and a clip to close the end of the tube and maintain the balloon at any desired distension, also an ordinary firm bandage. Last thing at night a couple of turns of bandage are fastened round the head over the eyes; a balloon is then slipped underneath it so as to cover the eye and by means of the tube the patient blows up the balloon until it exerts a moderate pressure upon the eye and eyelids. The end of the tube is then closed by the clip and the apparatus worn all night. The prolonged gentle pressure on the eyelids effects the cure.

INCOME TAX

Adjustment on Purchase of New Car

"T D N" bought a four seater car in 1918 for £262, and sold it for £45 in 1922, purchasing in replacement a four seater of another make for £336. He has claimed a deduction of £336-£45=£291, but the inspector refuses to allow more than £180-£45=£135 the £180 being the present price of a four seater of the make first bought.

* * We have to disagree with both! In our view the proper deduction for the cost of replacement as an expense of the year 1922 is £262-£45=£217. "T D N" is wrong, because when he purchased a superior grade of car he was raising the standard of his professional equipment by capital outlay. The inspector goes too far in the other direction, and his action does not accord with the official evidence given before the Royal Commission on the Income Tax, or with the present official practice as we understand it to be. "T D N" is also entitled to a depreciation allowance for the current year 1925-26 in respect of his present car, calculated as follows:

	£	£
Original capital expenditure on car	45	262
Deduct Receipt for sale	217	
Renewal allowance		262
		0
Add cost of new car		336
Allowance at 15 per cent		50
Value carried forward		286

Salary from Appointment

"T R A." inquires (1) as to the allowance of expenses incurred in qualifying for the appointment he holds, and (2) whether he can average his earnings.

* * The income derived from an appointment is assessable according to the rules of Schedule E which (1) allow expenses only if incurred wholly exclusively and necessarily in the performance of the duties of the office and therefore exclude expenses of qualification and (2) require assessments to be made on the income of the year and therefore so long as "T R A." derives income from 'employment,' his salary cannot be averaged.

Assistant's Salary

"PERPLEXED" states that A and B were in partnership and made up their accounts to December 31st, in September 1924, B retired and A took over the practice and employed an assistant. "A has been assessed for 1924-25 on the total profits" (on the usual average) less B's share from April to September, the assistant's salary being deducted as an expense.

* * There is one point we do not understand, the 1924-25 assessment is apparently on the average of the three years 1921, 1922, and 1923, and the assistant's salary would not be an expense in any of those years. A's liability to assessment is determined by his share of the average assessment but he has the right, under No 9 of the rules applicable to Schedule D, Cases I and II, of applying to have that basis set aside for the period from September, 1924, to April, 1925, and to have his liability adjusted to the amount of his earnings for that period, after deducting of course, the assistant's salary, etc. Strictly the right is exercisable by way of a claim to repayment of overpaid tax, but we believe that it is quite common in practice to arrange an adjustment before payment of the second instalment of the tax assessed. "Perplexed" might usefully bring the Inspector's attention to the section referred to above and discuss the matter with him.

LETTERS, NOTES, ETC

KENYA

MAJOR W. LLOYD-JONES D.S.O. late of the King's African Rifles writes to controvert the statement in our review of Dr Norman Leys's book on Kenya (November 21st p. 95), that there is no "desert" in that country. Although (he says) it is not necessarily all "sand" except in the Kavirondo country and coast belt land below 5,000 ft has no perceptible agricultural value and only affords a very meagre living to the scattered nomadic tribes.

MECHANICAL LOCOMOTION FOR ELDERLY PRACTITIONERS

A MEDICAL practitioner who in his youth, was very active and has crossed on his bicycle nearly every Alpine pass is now over 60 and weighs more than 13 st. He writes to report his experience of various accessory forms of locomotion which he has tried in his town practice where hills are steep and numerous and the traffic is heavy. He abandoned bicycling and at first carried on his professional work on foot but later tried two types of motor cycle and a small car. The lack of a chauffeur caused the abandonment of the car, and our correspondent felt that the motor cycles usurped control too much. Whereas he wanted to travel slowly, they tended to run away with him at corners. He finally tried a "cycloroid" which he found perfectly adapted to his needs. He can use it as an ordinary bicycle or by lifting a lever, as a motor bicycle. He can travel as slowly or as fast as he pleases, stop when he likes, and he feels master of the machine. He adds that it is a strongly built bicycle with a front wheel which can at will be converted into a motor wheel.

FACIAL IRREGULARITIES

DR J. STEWART MACKINTOSH (Hampstead, N.W.) writes. It is needless for Sir Arthur Keith to speculate on the cause of facial irregularities in the British. Alexandre Dumas solved the problem in his day. "Je remarquai que la déformation de la bouche si commune chez les vieux Anglais et les vieilles Anglaises, ne s'opérait qu'à un certain âge, et que tous les Anglais et toutes les Anglaises jeunes avaient en général, des bouches charmantes. Qui peut avoir déformé la bouche au point d'en faire un musée chez les uns, ne trompe chez les autres? C'est le th." (*Une Aventure d'Amour*)

GENERAL PRACTICE TO DAY

"ANOTHER JUNIOR G.P." writes. County council fees are quite inadequate. Two guineas is not a proper fee for a doctor who has to deal with a case of abnormal labour. Is "Junior G.P." (November 14th p. 928) aware that the Poor Law guardians are paying the ridiculous fee of 10s. 6d. to the parish doctor for attending a midwifery case?

CHRISTMAS CHOCOLATES

NEVER we imagine in the 400 years that have passed since Christopher Columbus first brought cacao from Mexico to Europe has this substance been more universally popular than it is to day. Cocoa as a beverage may perhaps be drunk less in England than it was a generation ago but chocolate sweetmeats seem to grow in favour with young and old as may be judged by the swarms of sweetshops in every street throughout the land. An agreeable package of chocolates and cocoa received from Bonville reminds us that Christmas is fast approaching and that the immense popularity of these preparations both as beverages and as eatables is due to the energy and enterprise of a few English manufacturers of whom the firm of Cadbury Brothers by general consent stands foremost.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 40, 41, 42, 43, 45 and 47 of our advertisement columns and advertisements as to partnerships, assistantships, and locum tenencies at pages 44 and 45. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at pages 207 and 225.

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL
MEETING, BATH, 1925

SECTION OF MEDICINE

Professor T R ELLIOTT, M.D., F.R.C.P., F.R.S.,
in the Chair

DISCUSSION ON HYPERPIESIA.

OPENING PAPERS

I—THE RIGHT HON. LORD DAWSON OF PENN,
G.C.V.O. M.D., F.R.C.P.

Physician to the London Hospital President of the Section

BEARING in mind that the subject it is my privilege to introduce is large and that our time is short, I must perforce confine myself to certain of its aspects

I will assume that hyperpiesia, in its developed form, is a condition *sui generis*, manifesting certain discomforts or disabilities and culminating, it may be, in heart disease or arterial degeneration or their varying consequences, that it is a condition distinct from chronic interstitial nephritis, though the two diseases may sometimes show so close a resemblance in their clinical behaviour as to be difficult of differentiation. I will deal first, and briefly, with certain physiological considerations

The circulation of the blood is maintained by a number of forces, there is the paramount force of the heart, and beyond this there are the elasticity of the arteries, the contractility of the arterioles, and the forces belonging to the capillaries and veins. In the capillaries not only does the internal friction of the blood contribute to the peripheral resistance, but there is a capillary tone produced by nervous or chemical influences. The veins also possess tone and the circulation in the larger veins is influenced by the thoracic movements

These several factors vary each in its prominence and contribution to the circulation of the blood in different healthy people. Pressure in the arterial system is maintained by the heart beat, which is an intermittent force, and by the peripheral resistance, which is a continuous force. The systolic or maximum pressure represents the force of the heart beat and the peripheral resistance together. The diastolic or minimum pressure represents peripheral resistance only.

On the supposition of the output of the heart remaining constant a limited increase of vaso-constriction will bring out, with and during ventricular systole, an extra quantum of elastic stretch in the arteries, which extra quantum will fade away during the subsequent diastole of the heart—that is, systolic pressure is raised but not diastolic. It might be argued that if the increase of vaso-constriction went further, the diastolic pressure would also exceed its normal—that, in short, the systolic and diastolic pressures represent a difference in degree of vaso-constriction. That this explanation is inadequate is shown by the fact that sometimes diastolic pressure will show an increase out of proportion to the systolic

Vaso-constriction may be increased either by increase of contractility or anatomically, by the thickening of the intima and a consequent narrowing of the lumen. The former involves hypertrophy of (muscular) tissue, and the latter degeneration of tissue

Arterial Pressure in Youth

I suggest that it will assist in the study of our problem if we pay special attention to arterial pressure in youth where tissue is pure and undefiled by degenerative processes. In later life hyperpiesia and arterio-sclerosis hunt in couples, and have a similar causation, such as strain or toxæmia, and although arterio-sclerosis is so often associated with low pressure as with high it is a common accompaniment of hyperpiesia in the middle-aged and elderly. Evidence of this abounds and does not require quotation

It is by the study of blood pressure in youth that we may hope to disentangle hyperpiesia from arterio-sclerosis and determine whether hyperpiesia has its beginnings in structural change or in faulty function

What should the Blood Pressure be?

The systolic pressure in infancy would seem to rise from a beginning of 55/40 at birth. It then increases, but by no means constantly, to the third decade. From the early twenties to 45 in the same individual it should not vary much. Most observers would put it at 115 to 130. If it were habitually over 140 they would not feel happy. I have estimated the blood pressure as a routine for some years, and my own experience would accord broadly with that statement. On exercise the normal blood pressure should rise with the pulse and respiration and return to normal within a few minutes of the resting position being resumed, in some healthy people there is a subsequent fall of pressure after exercise

On the other hand, Brandreth Symonds, with a large experience of life insurance, takes a stricter view. He points out that blood pressure varies not only with age but with build, and increases with weight as well as with years. Taking male lives accepted at standard rates and all builds, he gives the average systolic pressure from 123.5 (ages 15 to 19) to 135.3 (age 60 and over). He further states that a systolic pressure of over 140 at an age is suspect in insurance circles. If clinicians were to accept these views they would indeed have to be gloomy prophets

Alvater studied blood pressures on 1,500 freshmen at the University of California, and judged the normal average to be—for young men 124.7, and for women 114.6. He found, however, over 20 per cent of the examiners with a pressure over 140, and here and there pressures of 170 and upwards. No doubt some of these raised pressures were due to the effect of passing circumstances on impressionable youth, but when every allowance is made it remains a fact that high blood pressure is to be found amongst the young need produce no evidence of ill health, and is only discovered in the course of routine examination

Diastolic Pressure

The diastolic pressure has been less widely studied. I would suggest that in healthy males from 15 to 25 the diastolic pressure will be found about 75 to 80, and that it should not be beyond 85. From the age of 25 onwards one prefers not to see it beyond 90, and above 100 causes us uneasiness. The health limits of the diastolic are narrower than those of the systolic pressure. These figures are the readings at the commencement of the fourth stage, when the sound fades

The normal blood pressure of the healthy body would be expected to vary within comparatively wide limits, just as men's other physical characteristics do. The higher civilization goes, the broader the limits of the normal will become. I may illustrate this by referring, on the one hand, to a healthy vigorous family in which the father, even after the age of 50, the mother, and the grown up sons have none of them a systolic pressure above 110 and, on the other hand, to a family no member of which has a systolic pressure under 130

These examples prompt the reflections that vaso-constriction plays in some people a larger and in other people a smaller part in the circulation, and that it is difficult to say where normal blood pressure ends and abnormal begins. It looks rather as if hyperpiesia may begin as an exaggeration of a quality (too much of a good thing) and as something which begins in a realm of physiology and ends in the realm of pathology—that, in short, it is physiology gone mad

In order to study blood pressure in youth and the early stages of hyperpiesia I decided to investigate a group of school children, and this has been rendered possible through the kind and understanding support of the school medical officers, of the headmasters and headmistresses concerned, and with the valuable and valued help of a group of workers led by Dr Donald Hunter. The investigation took place in four schools—two secondary (boys and girls) and two primary (boys and girls). I will not take up the time of the meeting

with the details, which will be published on a future occasion, but will deal with the general results.

Taking these schools together we find a total of 650 examined—ago limits 10 to 17—and of these 52, or exactly 8 per cent, show a pressure above 130. Some cases show a rise in the diastolic pressure. A reading of 90 or above at so early an age is abnormal, and is of more serious import than a raised systolic, for it means that the minimum pressure within the arteries is high.

We next studied the distribution of the raised pressures. We could not identify hypertrophy with any particular physical type of child. The headmaster or headmistress made a selection of a small group of keen younger children—"nippers"—and amongst these hypertensives was not a feature, and this observation is confirmed by Dr. Peier. Stocks's valuable investigation seem to raise pressure ordinary examination seem to raise pressure. On the other hand, in the two secondary schools there were classes working for the Oxford senior local examination, and in these classes the incidence of abnormal blood pressure (that is, above 130) was more than two and a half times larger than the incidence for the two schools as a whole.

Now the issues which are attached to this examination are various, success comes with it not only a prospect of entrance to a university but a raising of social position for the pupil and indirectly for the parents. It is easy to understand that such a class would attract the intelligent and ambitious children, and how it would engender not only stirring but in some of them intentness and anxiety. In some temperaments this anxiety would relax in the intervals of work, in others it would not.

The conclusion I am inclined to draw is that the abnormal pressure is not produced by stirring, but is an existing tendency or trait made manifest and accentuated by the stirring. A rise in pressure occurs normally in anticipation of effort, and anticipation—the desire to forestall—plays in civilization an increasing part which shows reactions with bodies and minds of a certain physiological cast. I will postpone to another occasion consideration of the relation of emotion to vaso-constriction, a matter to which Golla has made valuable contribution in his Croonian Lectures.

It is impossible to suppose that these 52 young people—this 8 per cent—having the appearance of health and vigour, but with abnormal arterial pressures, can all be the victims of a degenerative process. Rather, I suggest, do they show an inborn peculiarity of function—and in some cases a family tendency. Then arterioles have a selective responsiveness. Just as some hearts are too responsive and easily get tachycardia or deranged rhythm, the arterioles of some people become too easily overthrown.

But this peculiarity of function may become so pronounced as to produce damage, and thus disease may ensue. We see a comparable happening in the case of people with so-called "bad circulation." One can observe all the gradations from cold extremities, raw-beef hands, chilblains of varying severity, to typical Raynaud's disease. Some of these 52 young people are the potential hyperpiesics of later life. With many of them the tendency may be corrected by educational treatment and a careful choice of their careers.

What a field for preventive medicine is this! As long as the vaso-constriction relaxes within reasonable time after the occasion of the overtone has ceased, the arterial pressure, though high, remains flexible. But with some the vaso-constriction seems, by contact with the world, to be provoked by slighter and slighter stimuli—it is as if the patient becomes sensitized, and then the vaso-constriction tends to persist after the cause of the increased pressure has been removed. Thus arises an increasing habit in the high blood pressure, and then begins the era of strain which leads to disease.

The correctness of these views may be tested by a more detailed investigation amongst the 52 young people already referred to. This has been carried out sufficiently to justify my advocacy, though I hope with further time and labour to speak with greater authority. Their blood pressure readings were reported under varying conditions and at different times. Amongst these young people 9 cases of fixed high pressure were selected, the names of these 9

were examined for albumin, and, if the latter were present, for casts. They have been examined by radiography, the electro-cardiograph, and by chemistry. I will summarize the results.

Their ages varied between 15 and 19.

Their pressures varied between 130 and 185 systolic and 70 and 115 diastolic.

In most of them the radial arteries were palpable, in none of them hard. In 6 the aortic second sound was accentuated.

In 4 the left ventricle was definitely hypertrophied, in 1 it was doubtful and in 4 normal in size. 3 had blood urea over 0.050 per cent, in spite of good urea and good dye excretion. None had blood urea over 0.0038.

None showed a dye excretion below 50 per cent, and only one had urea concentration below 15.

In 3 of the cases I had the advantage of careful observations having been made by Dr. Stocks years ago.

- A Blood pressure in 1922 = 155/98, now 160/100 and definite hypertrophy
- B Blood pressure in 1922 = 155/98, now 160/100 and definite hypertrophy
- C Blood pressure in 1923 = 146/110, now 185/110 and definite hypertrophy

These three last cases are especially valuable because their blood pressure may be taken as having been on a high plane for some years. The last named (C) is a bank clerk, a well made youth, who plays games, and has rather a pale complexion, he stands out in the list of 9 as having a definitely high blood urea—namely, 0.070. His blood urea acid was not raised, being 0.0030, the concentration test was normal and the dye excretion 50 per cent. He impresses me as the type of case whose clinical picture will be difficult at a later stage to distinguish from that of interstitial nephritis. It is a case in which I would judge that the kidney will take command at an early stage, or, as some authorities would reason, the infective factor has got grip of him.

It is to be noted that in none of these 9 cases (and I have others which bear out this statement) was the blood urea acid over 0.0038 (N.B. normal limits of urea acid in Canada 0.005). This is of interest in view of recent work in Canada and elsewhere in which it has been suggested that raised urea acid content can produce a pressor influence.

As one would expect, there is amongst these cases considerable variation. As a series they seem to merge, on the one hand with the physiological, and on the other hand with a pathological state. It is, I think, a right conclusion that some of them show signs of strain and are passing into the realm of disease—they are predestined. The most definite change is cardiac hypertrophy, which the continual over-tone of the arterioles has produced. With cases so mild can summary pathological evidence is lacking, but I can produce such evidence in the following account, which describes the same process at a later stage.

At the age of 11 a girl X.Y. began to have migraine headaches. After menstruation was established the liability to migraine was more noticeable and especially prior to the periods. At the age of 14 the headaches became more frequent and interfered with her work. At the age of 19 in the year 1922, she came under my observation when I found a blood pressure as high as 240 systolic and 140 diastolic. There was slight cardiac enlargement, the accessible arteries were soft. Rest in bed did reduce the pressure but not below 150/110, and then only temporarily. There were sometimes a trace of albumin and a few hyaline casts in the urine. She had had a severe attack of scarlet fever in childhood. A suggestion was made that she was a case of slowly progressive interstitial nephritis but neither the clinical nor anatomical picture fits in with that suggestion. Her youth was not only that of years but of appearance colour and attitude of mind.

This year (1925) it was noticed that her headaches were fewer and otherwise she felt well provided she was protected from too strenuous work. Nevertheless the cardiac hypertrophy was more marked and when up and about, although doing no work the blood pressure was often 240/140. So it was resolved to decapsulate the kidneys. This was done and at the same time portions of the kidney were secured for examination. The sections showed the following: (1) The most marked feature was hypertrophy of the tunica media of the larger arteries. (2) Slight changes including some fatty degeneration of the intima of the smaller arteries. (3) Patches of partial atrophy of tubules due to infiltration by small round cells (early fibrous changes). The latter change I should regard as due to defective blood supply though some might interpret it as evidence of infection. Changes characteristic of interstitial nephritis were absent.

This case represents a later stage of the condition noted in the school children. Not only the systolic but the diastolic pressure was considerably raised and in a measure

† The full report of the sections by Professor Turnbull will be published later.

fixed, and habit has become a vice. Structural changes have ensued—the effects but not the cause of the pressure—though they have now stereotyped the condition and henceforth will go far to determine the future history of the patient. If one tries to forecast that future, one visualizes increasing patches of fibrosis and atrophy of tubules, the work of overaction thrown on diminishing areas of renal tissue and the kidney influencing the clinical picture in increasing measure. This influence includes an increased drive of the heart, perhaps due to failing kidney function. In short, the kidney takes command.

If one puts the school children referred to above and X Y side by side, there is every gradation from normal pressure to fixed high pressure and structural changes—potentiality passes into actuality.

The following brief observations, made among a group of adults, are comparable with those made among the school children already referred to.

Three hundred men, belonging to an active and responsible calling in which a good standard of health is expected, were examined. Of these, 35 had a systolic pressure above 140 and of the 35 20 were aged 40 or under—that is, rather more than 6 per cent of these men under 40 years of age had raised pressures. These pressures varied from 140 to 190 systolic. None of these men with raised pressures showed any signs of ill health though one or two of them were beginning to show signs of cardiac hypertrophy. They would seem to belong to the same category as the hypertensive school children.

The high blood pressure which becomes manifest for the first time in middle or later life has probably more varied explanations. No doubt in some instances it has existed since youth and loomed larger with the years, but in others it supervenes after years of normal pressure. It may be that the plain muscular tissue develops too great a responsiveness, just as asthma can develop in later life, but here degeneration and narrowing of the smallest vessels may play an early and prominent part, following more or less closely behind the hyperpiesia, whereas in the youthful cases such changes are a later development. Moreover, here we may find association with sedentary life, waning of sexual activity, obesity, and the stockiness and fixity which are apt to arise in middle life. All of these suggest on the one hand errors of metabolism or internal secretion, or on the other hand toxæmias. MacDonald's work is of interest in this connexion.

A hard working man at the age of 40 had a blood pressure of 160 at 42 it was still 160 at 43 it was 170/90 and at 45 185/112. At the time of the last observation the blood urea and uric acid were within the normal.

Proneness to vaso constriction, like some other peculiarities, may be inborn. Such it must be when it occurs in school children. Strickland Goodall has shown that high tension may exist in babies, and in this connexion one is led to reflect whether certain fatal cases of idiopathic hypertrophy of the heart in young children which have been reported may not have been due to high arterial pressure.

Hyperpiesia may be a family tendency, the case of X Y is an example of this. The family record is as follows:

Father, aged 47	blood pressure, 166/120
Mother, aged 46	, " 160/100
A younger sister	, " 138/90

Among the relatives of three of the school children we investigated were discovered a brother of 20 and a sister of 23 with high tension. I am indebted to Dr Charles Weber for another example:

Father aged 56	blood pressure, 215
Mother, aged 49	, " 182
*Sister aged 20½	, " 130
*Brother aged 20½	, " 140
Sister, aged 17½	, " 135

* Twins

O'Hare has recorded others.

On the other hand, there are families in whom a low pressure prevails. I suggest that the family tendency may in some cases be so strong as to show itself, come what may, whereas in other and more frequent instances it will only take control if stimulated by the temperament or by the environment or both, of the individual.

As regards the ways and means of such vaso-constriction it may be due to chemical agencies (to pressor substances—

for example, guanidine derivatives) in the blood, or it may be due to the influence of the higher centres—that is, to an innate or inherited habit. The search for pressor substances has so far been limited and not altogether encouraging.

In conclusion, hyperpiesia is not a condition with a defined territory, it has no threshold. It begins as a habit of body and mind which is not disease but may lead to disease, it creeps into our lives without our ken—while we are fit and efficient, it gives no evidence of its presence or only such signs as a healthy-thinking individual would ignore, and unless some lucky defect in health brings about a medical examination, and therefore a disclosure, no revelation occurs until definite damage to the life compels an acknowledgement that the frontier of health has been crossed and return will be difficult or impossible.

University College, London

THE PHYSIOLOGICAL FACTORS IN HYPERPIESIA

THE arterial blood pressure is the resultant of two factors—namely, the output of the heart and the peripheral resistance. The output of the heart depends on the inflow, and is chiefly conditioned by the muscular activity of the body and by the blood volume. The peripheral resistance is maintained by the tonic contraction of the arterioles, especially of the splanchnic area, and is thus under the constant control of the vasomotor centre working through the sympathetic system. A fairly high arterial pressure is necessary for the maintenance of a blood flow through the working parts of the body according to their activities. Although the blood flow through each part is regulated by variations in the calibre of its nutrient arterioles, these variations would be without effect unless a constant head of pressure were maintained in the main arteries. In the normal individual this pressure varies with the heart beat between 85 and 120 mm of mercury. Since its height depends on the average state of contraction of the arterioles of the body, the height at which it is set must be regulated according to the needs of the vasomotor centre. The brain with the vasomotor centre require a constant supply of oxygen at a fairly high tension. Since they are the master tissues and control the blood supply to all other parts of the body their own supply depends only on the pressure in the circle of Willis—that is, on the general arterial pressure, thus they will maintain constant whatever the needs of the other tissues. Thus we find that even in failure of compensation they will not allow this pressure to drop so as to relieve the heart, they will maintain this pressure by shutting off the other regions of the body, so

as to diminish the total output of the heart necessary to maintain a normal arterial pressure.

This insistence of the vasomotor centre on its average and constant blood supply is strikingly shown in some experiments lately carried out by Anrep and myself. In the ordinary animal any change in the circulation through the brain will at once compensate itself by changes in the circulation in other parts of the body, and we get a complex series of events which it is difficult to unravel. In order to study the influence of alterations in the circulation of the vasomotor centre on the circulation through other parts of the body we must provide the brain with a blood supply which is entirely under the control of the experimenter, so that any change in the general circulation evoked by altering the blood supply to the vasomotor centre will not have its normal results on the circulation through the centre itself. This can be accomplished by using the heart-lung preparation from one dog to feed the brain

FIG 1.—Diagram of the crossed circulation. A, perfused head B, part of animal supplied by its own heart. SCA, brachiocephalic artery. SVC, superior vena cava. Ao, descending aorta. IVC, inferior vena cava. H-L, heart-lung preparation supplying blood to perfused head (lungs not shown).

of another dog in which the heart is maintaining the circulation simply through the trunk and limbs (Fig 1). The results on the general circulation of altering the blood flow through the brain and vasomotor centre are illustrated in the accompanying diagrams (Figs 2 and 3). These show that the vasomotor centre is acutely sensitive to the slightest alteration in the blood flow through it. The smallest increase in this flow causes general vaso-dilatation, and therefore a fall of blood pressure, while the slightest decrease brings about general vaso-constriction and a rise of blood pressure, and these effects are permanent—that is, last as long as the alteration which is effected in the vasomotor centre.

In hyperpiesia we do not dealing with the temporary rise of blood pressure such as is brought about in the normal individual by increased activity, especially of the muscular system or by chemical means, such as setting free adrenaline, but the blood pressure is set permanently at a high level, round about which occur the physiological fluctuations of pressure. Such a setting of the blood pressure at a high level cannot be brought about by any local alteration in the peripheral circulation. We may have claudication of the lower extremities, till the legs become gaugrenous and drop off, without any lasting rise in the arterial blood pressure. The setting of the arterial blood

pressure at an abnormally high level must mean that at the normal pressure in the circle of Willis the vasomotor centre is not receiving sufficient blood for its requirements.

FIG 2.—Effect of abrupt rise and fall of the blood pressure in the perfused head (A) upon the blood pressure in the rest of the animal (B). Both vagi cut.

There are many ways in which such a state of things might arise, and I do not believe that the condition of hyperpiesia will be found to be unitary in its pathogenesis.

FIG 3.—Effect of slow changes in the blood pressure in the brain vessels (A) in producing the reverse compensatory changes in the systemic circulation (B).

The condition in which the normal arterial pressure was not sufficient to drive an amount of blood through the capillaries of the vasomotor centre sufficient for its needs might arise in various ways.

1 In the first place gross lesions in the arterial trunks might diminish the average pressure in the circle of Willis or in the arteries of the brain, either by abolishing the elastic resilience of the arteries by which the blood pressure is maintained between each heart beat, or by actual partial occlusion of their lumen. This condition is, however, well known, and hardly comes under our consideration to-day.

2 It is conceivable that we might have a condition of claudication in the vessels of the vasomotor centre similar to that which frequently occurs in the lower extremities. This might have its origin in a subinfective process arising from the internal surface of the body and leading to proliferation of the intima and narrowing of the lumen of the arteries. The natural reaction of the vasomotor centre to such a condition would be a permanently raised pressure in order to drive the normal quantity of blood through the narrowed channels by which it is supplied.

3 A contraction or spasm of the muscular coat of the arterioles to the brain and vasomotor centre has played at different times an important part in our pathological speculations, even since the time of Brown-Sequard. I must own I am sceptical as to the probability of such a condition existing at any rate as a permanency. The contractility of the arterial wall does not play the important part in the brain that it does in other parts of the body, and a continuous contraction of the arterioles to the vasomotor centre against the requirements of this centre and the

needs of the body as a whole seems an unlikely explanation of the phenomena of hypopiesia.

4 All the mechanisms for the regulation of the activities of the heart and arteries are directed towards the maintenance of a blood flow through the capillaries in accordance with the needs of the tissues they supply. First among these needs are those of the vasomotor centre and brain. There is evidence that in many parts of the body—perhaps in all—the capillaries are endowed with contractility, and this property must be a considerable factor in regulating the migration of the tissues according to their activities. Any such contraction of the capillaries to the vasomotor centre would evoke as an immediate response a rise of arterial pressure lasting as long as the contraction of the capillaries. But we know that the capillaries are susceptible to other chemical influences which alter their permeability—that is, the amount of blood fluid which filters through their walls. A familiar example of such a change is the wheals produced in the skin as a result of ingestion of certain animal poisons, or by the local injection of substances such as histamine. Any similar change in the capillaries to the brain would be fraught with evil results for the circulation through them, for it must be remembered that these capillaries run in a pericapillary lymphatic, increased exudation would cause a rise of pressure in the lymphatic and a corresponding narrowing of the lumen of the capillary. I would suggest that such a condition of altered capillary wall is responsible for the high arterial pressure which is the invariable concomitant of certain toxic conditions, such as uraemia and the toxæmia of pregnancy. In both of these the high pressure which I have attributed to interference with the capillary circulation to the vasomotor centre is accompanied by well marked signs of deficient circulation through other parts of the brain, such as headache, transient loss of speech, various paralyses, and convulsions, and we know that in the toxæmia of pregnancy, at any rate, all these symptoms may subside with the termination of the pregnancy. It is perhaps not without significance in this regard that records of *post-mortem* examinations of patients who died from uraemia or eclampsia often speak of a "wet brain"—that is, one in which there is overfilling of the perivascular lymphatics.

5 It is impossible in any consideration of the causes of hyperpiesia to exclude the question of the part played by the kidneys. If we exclude altogether the acutely toxic conditions, such as uraemia, there remains still a large body of cases in which kidney changes of a low order are associated with raised blood pressure. Although opinions differ on this point and experiment has not said its last word on the subject, there is considerable evidence that progressive occlusion of the vessels to the kidney, which we might call claudication of the renal vessels, or destruction of the glomeruli, may give rise to progressively increasing arterial blood pressure. Cohnheim regarded this condition as a physiological reaction for the purpose of increasing the pressure in the remaining glomeruli, thus favouring the elimination of the soluble waste products of the body. But it must be remembered that even if this account of the sequence of events is correct, complete obstruction of the renal circulation would not by itself cause a rise of blood pressure. It can only do so indirectly by the results of this obstruction on the vasomotor centre. One can hardly imagine that in the initial stages of such a disorder, when the patient remains in apparent health for years, there is a toxic alteration of the capillaries of the brain and vasomotor centre leading to increased transudation and capillary obstruction. The only possible explanation for such a condition that I can see at present is that the retention of substances which should be excreted with the urine has a direct effect on the vasomotor centre itself. It may diminish the rate at which this centre takes up oxygen, or may impede in some way the transference of oxygen from the blood in the capillaries to the nervous tissue of the centre, or finally it may raise permanently the irritability of the centre.

Whether alterations in the kidney are ever the prime cause of the changes associated with hyperpiesia seems to me still an open question. The point I have tried to insist on in this communication is that the causation of hyper-

piesia must be first sought in the vasomotor centre. The changes in the circulation through the brain and the vasomotor centre may be primarily local or may be secondary to changes in other parts of the body, such as the kidney. But no pathology will be adequate which does not take into account the sensitiveness of the vasomotor centre to the changes in the circulation through it which determine the height at which the arterial blood pressure is set. The part played by each and any of the factors I have enumerated can only be decided by the continued labours of the morbid anatomist in association with experiment in the laboratory and the wards.

III—H. BATTY SHAW, M.D., F.R.C.P.,

Physician, University College Hospital and Brompton Hospital for Consumption

THE FEATURES OF A HYPERPIESIC CRISIS

As a contribution to this discussion I will detail the features of a hyperpiesic crisis in a patient who, while under treatment, presented a remarkable clinical picture.

A clerk, aged 59 years, was observed to become less keen about the discharge of his daily duties and complained of inability to grasp the details of his work. The effort to get off to business and catch the usual train was so great that after several months he declared he was quite incapable of making the attempt to start. His employer had found him inefficient and had had to relieve him. During his stay at home for many weeks he complained of sensations of all-goneness of sinking at the epigastrium of depression, of somnolence in the day and restlessness at night. Simple hypnotics were used but soon lost their effects, and the doctor in charge, fearing to use the more drastic ones, asked for his admission to hospital.

When admitted the symptoms described continued and, in addition, he was found to be delirious and drowsy. He could be roused but showed symptoms of motor and sensory aphasia. A trace of albumin was found in the urine, but no sugar, and white patches were found in the neighbourhood of the maculae. He was dyspnoeic and had swelling of the feet, occasionally he complained of headache. The cardiac impulse was heaving and placed in the fourth space in the left nipple line, the brachial arteries were tortuous, the second aortic sound was accentuated, no murmurs were heard. The pulse was regular and 96 to the minute, the respirations were 28 to the minute and a pleural effusion was found at the right base behind. The temperature was 97°. The pupils were pin point and did not react to light or accommodation. Kernig's sign was present, and the plantar responses were flexor. The systolic blood pressure was 250 mm.

The following day two pints of serous effusion were removed from the right chest, the fluid was sterile and showed no excess of cells. He slept well that night.

Thirty-six hours after admission he suddenly became unconscious and remained so for twenty-four hours, but moaned and made so much noise that he was given 1/75 grain of hyosine. He continued to groan and constantly put his hand to his head, he was also incontinent of faeces. As he had passed no urine since the morning of that day, a catheter was passed, but only 2 to 3 ounces of urine could be obtained. It looked normal, except that it showed a good cloud of albumin and readily reduced Febling's solution. It was free from acetone. The same sample of urine was found to be free from casts and organisms, and gave a positive fermentation test. Forty-eight hours after admission cerebro-spinal fluid was removed by lumbar puncture. It escaped under low pressure, was found to show no excess of cells, was sterile, and the globulin test was negative. The Wassermann test was negative. Venesection was performed to the extent of 6 ounces, and 100 c.c. of blood was found to contain 70 milligrams of urea.

During the period of coma the blood pressure fell to 124 mm. in systole, the urine remained scanty, the pulse reached 100 to the minute, the respirations at first reached 36 to the minute and then returned to about 25. The temperature which had hitherto been subnormal, now rose to 100.2°. He was infused with 2 pints of normal saline solution.

Seventy-two hours after admission he put out his tongue when requested to do so, but did not recognize his relations. In a few more hours he became quite conscious, had a large action of the bowels and passed urine spontaneously. In twenty-four hours the total reached 1700 c.c. The following morning the blood pressure had reached 228 mm. in systole and the crisis was at an end.

So ill was he during the crisis that it was expected that he would die. He slowly recovered with the return of the blood pressure to its usual height of about 250 mm. on the fifth day after admission the urine being normal in amount and only showing albumin occasionally. The pulse rate which had been excessive since admission, reached 80 to the minute, the respirations 20 and the temperature oscillated from normal to 99°. The oedema of the ankles lessened, the pupils reacted normally, and the Kernig sign disappeared. The blood sugar at this date was 0.14 per cent, but the urine was free from it.

On the eleventh day after admission the blood sugar curve indicated true diabetes, but no sugar was found in the urine. The maximum sugar in the blood two hours after the ingestion of 40 grams of glucose, was 0.23 per cent. A pint of serous fluid was

again removed from the right chest, and was again found to be sterile.

Although the patient had improved so much since the crisis, his condition was never sufficiently satisfactory to allow him to leave the hospital. Sixteen days after the crisis the blood urea was 20 mg per 100 ccm of blood, and at a later date was 33 mg. The blood pressure became higher than on admission, reaching a maximum of 284 mm, and on one occasion shortly before death, it suddenly fell again to 184 mm, but without loss of consciousness. Gradually the dropsy increased, effusion occurred at the left base, and albumin was constantly present in the urine. After seventy-nine days in hospital he gradually became drowsy and sank, the blood pressure being maintained at a high level until shortly before death.

At the post mortem examination the heart weighed 24½ ounces, it showed hypertrophy, but otherwise was normal. The lungs were oedematous, and fluid was found in the pleural cavities. The kidneys only showed slight fibrosis. The brain was quite normal.

On December 19th the blood urea equalled 20 mg, and on February 7th 33 mg

Comment

Obviously it was difficult to say at the time of the crisis what was the cause of such an extraordinary clinical picture. Cerebral haemorrhage was thought of, but was excluded by the fact that the temperature did not rise excessively, and the cerebro-spinal fluid contained no blood.

The presence of sugar in the urine during the attack, and the discovery when the attack had passed off of a typical diabetic blood-sugar curve, were most unusual, and have not been observed in other cases of hyperpiesis crises. Despite the presence of excessive sugar in the blood when the attack had passed off, the renal threshold was apparently high enough to prevent sugar occurring in the urine, but in the attack the threshold was apparently lowered owing to some temporary disturbance of the kidney function, this possibility being supported by the discovery of a high blood urea content during the crisis.

It looks as if the crisis occurred owing to a sudden relaxation of the peripheral vasomotor tone which allowed the patient to bleed as it were into himself, for the pulse rate was increased before and during the attack, and gradually assumed the, for him, normal rate when he regained consciousness. This would agree with possible

histamine poisoning, or it might have occurred as a result of a terminal infection which raised the temperature and caused pleural effusion.

IV—OTTO MAY, M A, M D,

Medical Officer, the Prudential Assurance Co, Ltd

MORTALITY IN RELATION TO HYPERTENSION

My remarks will be limited to the statistical relation between hypertension and mortality. They are based on proposals made to the Prudential Assurance Company from 1920 to 1924. The reason for choosing such a recent period is that at the beginning of 1920 we adopted a system of coding various facts with regard to each policy issued, thus facilitating the investigation of statistics regarding these facts. One of these is the "systolic blood pressure" on the policy card there is recorded whether or not the pressure was measured, and, if measured, whether it was (a) below 140 mm, (b) 141 to 170 mm, (c) above 170 mm. The duration of the policies has therefore been necessarily short, and I hope to be able, in the course of a few years, to present more authoritative figures, representing a longer and fuller experience. The present must be regarded in the light of a preliminary or interim report.

I should like to point out, before giving any actual results, that no statistics based on examination for life assurance should be interpreted too meticulously. The examinations are made by a large number of medical men, varying considerably in experience and, I may add, in the skill and care which they bring to the work, with the result that the data do not conform to any uniform standard of exactitude. It is curious how long it is taking to establish the sphygmomanometer as a clinical instrument second only in importance to, if not equal to, the thermometer and the stethoscope. A considerable proportion of general practitioners do not possess the instrument at all, and regard it, in the actual words of one of our referees, "as all right for the consultant, but no use to the general practitioner." It is, of course, quite true that its findings must be interpreted intelligently, that it is not infallible in its aid to diagnosis and prognosis, but surely the same applies to the thermometer, and still more emphatically to the stethoscope. I feel that we are helping appreciably in the popularization of the sphygmomanometer by requiring the blood pressures, in suitable cases, from thousands of our local medical referees.

Another probable source of fallacy, besides inexperience or faulty methods on the part of the examiner, is the fact that, in many cases, only a single reading is possible. There can be no doubt that a first reading in a subject of excitable temperament is liable to be higher than subsequent ones. The mean of, say, three estimations on consecutive days would probably give a truer measure of the average systolic pressure than a single reading does, but the exigencies of life assurance examination permit this only in exceptional cases, in most we have to be content with the single reading.

With regard to diastolic pressure, the difficulties are, of course, even greater in getting figures of any value. It is only in a small minority that any estimate of it is given, and we have not attempted any statistical work on the scanty material available.

I have thought it right to draw your attention to the possible fallacies in the data on which the following figures are based. But, in statistics, the larger the number of cases on which they are based, the less is the importance of individual errors. As will be seen, the results show so uniform an increase of mortality as the arterial pressure increases that they afford ample confirmation of the current view that increased systolic pressure is a definite handicap to longevity. I need, perhaps, hardly explain that in the following statistics the ratio of actual to expected deaths is worked out from actuarial tables, which take into account the age distribution of those "exposed to risk."

In the period under survey policies were issued on persons of 40 and over to the number of 106,507, comprising 84,700 males and 21,807 females. Of this number, the systolic arterial pressure was recorded only in 20,260 cases—17,760 males and 2,500 females—that is, only in about

19 per cent. At the present time the proportion is gradually increasing as the result of our persuasive efforts with our referees.

Systolic Arterial Pressure	Males		Females		Total
	Entrants	Per cent	Entrants	Per cent	
Under 140	13 375	75.3	2 066	82.6	15 441
141-170	4 073	22.9	1 399	16.0	4 472
Over 170	312	1.8	35	1.4	347
Total	17 760	100.0	2 500	100.0	20 260

These figures confirm the view, commonly held, that the pressures in women tend to be lower than in men, though no attempt has been made to analyse the figures in each group according to age.

With regard to the mortality actually experienced in these groups during the period under review, the actuarial investigation resulted as follows, taking the figure 100 as the ratio of actual to expected deaths for our ordinary branch policy-holders medically examined at entry over this period:

	Male and Female Combined	Male Only	Female Only
1 S.A.P. not recorded	97.1	103.3	77.2
2 S.A.P. under 140	102.8	105.4	83.8
3 S.A.P. 141-170	133.6	133.1	139.5
4 S.A.P. over 170	219.6	255.4	—
5 S.A.P. 200 and over	827.5	—	—

These figures confirm, so far as they go, the view that high blood pressure is unfavourable to longevity, that the outlook gets rapidly worse when the pressure is over 170, and that at 200 and over the mortality is no less than eight times the normal.

The last group needs a little further explanation. It includes some of the cases comprised in Group 4 (170 and over), and, in addition, some who were examined, but to whom no policy was issued, either because they were declined outright or they did not accept the terms offered to them. A special register of such cases was kept, and in March last inquiries were instituted through our local representatives as to whether these people were (1) alive or dead, (2) if dead, the cause and date of death. This was done only in the case of those who had been examined not less than a year previously. In some cases no information was obtainable, but we succeeded in following up 75 of them, and the actuarial analysis of the experience showed the ratio of actual deaths to what would have been expected at our normal rate of mortality to be no less than 827.5 per cent.

Out of 130 cases collected with a systolic pressure of 200 or over, the position with regard to albuminuria at the time of examination was as follows:

	Number	Per cent.
Albumin absent	95	71.5
Trace of albumin	20	15.4
Albumin present in appreciable quantity	17	13.1
	130	100.0

Of 16 deaths of patients in whom the systolic arterial pressure was 170 and over the certified causes were as follows:

Cardiovascular diseases—	5
Cerebral haemorrhage	1
Cerebral thrombosis	1
Cerebral embolism	1
Syncope	2
Endocarditis	1
Myocarditis dropsy	1
Arterio-sclerosis	1
Thoracic aneurysm	1
Uremia	1
Cancer of caecum	1
Postero-lateral sclerosis of cord	1

Of the above 16 cases only 1 showed any considerable albuminuria at time of examination, in 2 others there was a "trace," and in the remaining 13 it was described as "absent."

Our difficulty as physicians arises, of course, in any attempt to apply statistical findings to individual cases. Most of us know of many cases in which a pressure of 200 to 250 is consistent with many years of active life, to an advanced age. I myself have watched a man of rather "plethoric" type who, nearly thirteen years ago, at the age of 65, had a "haemoptysis of high tension," and was found to have an enlarged heart, leathery arteries, and a systolic arterial pressure of 190. He is still alive and pretty active at the age of 78, and his pressure has never been below 180. I have similarly observed, for the last five years, a man now 56, whose systolic pressure has been maintained throughout at 200 to 230. In neither case is there any evidence of renal disease. And so with many more.

My own impression is that if we find a persistent pressure of 240 or over we can, with little fear of error, venture to ourselves a prognosis that the patient will be dead within two or three years, but that he is a rash man who will attempt to predict, from the pressure alone, the expectation of life of an individual with a pressure less than this.

V—GEOFFREY EVANS, M.D., F.R.C.P.,

Assistant Director of the Medical Unit and Assistant Physician to St Bartholomew's Hospital

To avoid ambiguity about the subject of this discussion I would define hyperpiesia as simply a condition of persistent hypertension, it is not necessarily a condition of permanent hypertension, as a previous speaker suggested. I think that any systolic pressure that is persistently as high as 170 mm Hg or over comes into the category of hyperpiesia.

In contrast with hypopiesia, hyperpiesia is a condition of disease, Sir Clifford Allbutt, who first recognized the condition, described it as a morbid series, because it not only has clinical characteristics by which it can be recognized, but it also runs a certain clinical course. Its first clinical characteristic is a persistent high blood pressure, its second, described once by Dr. Batty Shaw as its hallmark, is left ventricle hypertrophy. This may also be evident in an electrocardiogram, and the enlargement of the heart can be verified by x-rays. The second aortic sound is ringing, the radial pulse is hard and sudden, or small and contracted, the retinal vessels are pale and contracted, and there may be retinal arterio-sclerosis. The name is generally unimpaired in colour and specific gravity. It may contain a trace of albumin, and the presence of sugar is not very uncommon. When it is well established it is easily recognized as a very definite clinical condition, and for the purpose of my contribution to this discussion I would contrast it with migraine. Migraine is an equally definite clinical condition, which is distinguished by its characteristic symptoms, hyperpiesia is distinguished by its characteristic signs. Migraine is transitory, hyperpiesia is persistent, though not necessarily permanent. It is not possible to determine in a dead body whether there was migraine during life, it is possible, however, in the case of hyperpiesia, to recognize it after death by its morbid anatomy. In other words, definite structural changes are associated with hyperpiesia, and by examination of a dead body it is possible to say whether or not hyperpiesia was present during life.

The most typical case is one in which death has occurred from cerebral haemorrhage or heart failure, or, it may be, from intercurrent affection such as pneumonia or septicaemia. I am not sure if Sir Clifford Allbutt's distinction of it from Bright's disease will ultimately hold good, for I think that I have seen cases of hyperpiesia terminate in uraemia (with marked urea retention), but I cannot speak with certainty, as I have not seen the post-mortem examination of such a case.

Whatever the nature of the terminal event, characteristically the patient is beyond middle age, well nourished, even plethoric, and above the average in height and weight. On exposure of the viscera the heart is found enlarged, and weighs more than 15 ounces. The enlargement is chiefly

due to hypertrophy of the left ventricle the valves are healthy, and the myocardium is thick and firm. Some of the larger arteries may be obviously thickened to the naked eye; there may be a visible thickening of the aorta, and when the splenic artery or other arteries are laid open longitudinally the inner surface may appear transversely ridged, apparently owing to muscular hypertrophy. When the spleen and kidneys are cut through, the smallest visible arteries can be seen to protrude beyond the cut surface like tiny quills. In other respects the kidneys may appear normal in size and colour, but their surface may be very finely granular, or they may be scarred by occasional old infarcts. On section the kidney is often normal, and the cortex retains the appearance of health in its fine radial striation, its thickness, and contrast to the pyramids.

On microscopical examination the most important feature is the condition of the smallest arteries and arterioles. It has been described¹ under the term of "diffuse hyperplastic sclerosis," and there is no need to repeat this description now.

The important fact which I wish to bring forward is that hyperpiesia has a morbid anatomy by which it can be recognized after death. I can imagine that this change of structure is not present in every patient who dies with hyperpiesia. It is not necessary to explain every change in function by postulating a change in structure. Thus there may be persistent hypertension (due to persistent increased activity of the vasomotor centre, as Professor Stirling has suggested), and persistent increased tone in the peripheral vessels without any alteration in their structure. In my experience, however, a change in structure has always been present, and I regard the association of this change in vascular structure, which is described under the term "diffuse hyperplastic sclerosis," to be coincident to the change in vascular function found in "hyperpiesia." There is no necessity for regarding the one as the outcome of the other, it is simpler to regard both change in function and change in structure as the effects, possibly simultaneous, of a common pathogenic agent.

THE ELECTRIC TREATMENT OF HYPERPIESIA

My apology for introducing the subject of electrical treatment of hyperpiesia is to be found in the absence of any mention of it in most of the scientific books and papers dealing with the subject which have appeared during the last twenty years. My justification for introducing it is to be found in one sentence of the last work,¹ recently published, of that great teacher, Sir Clifford Allbutt: "d'Arsonvalization is the most valuable immediate aid we possess for hyperpiesia." Sir Clifford Allbutt, writing to me two years ago on the subject of electrical treatment, said

"I have never written on high pressures without advising it (as I did not in my big book [?], well that is twelve years ago). In more than one recent published paper I have said that it is the one means that I have known (since it was first recommended) which does influence the high pressure."

What need have we of further witnesses?

In a paper I contributed to the *Clinical Journal*—I said: "When a high tension is sought to be lowered, d'Arsonvalization has a wide sphere of usefulness." Unless the abnormal tension be compensatory, efforts should be made to reduce the abnormality. It is now generally conceded that electrical currents have the power of modifying pathological arterial tension and yet have little or no effect upon normal blood pressure. And indeed the same has been observed of the action of digitalis.²

May I here forestall a criticism which has so often been levelled at the head of the electrotherapist who mentions electricity as a means of reducing blood pressure? It has often occurred to me. The objection is that it is not every case of increased blood pressure that is suitable for reduction, or that it is not advisable to reduce the increased tension in every case. Let me say at the outset that this is admitted. Where, for instance, there is a failing ventri-

cular compensation we know it would be harmful, and the mention to-day of electricity in this connection, as in many of the past, is limited solely to those cases in which the physician has come to the conclusion that the patient would benefit were his pressure reduced. Parenthetically it may be mentioned that in electricity there is a simple means of determining whether or no it would be wise to attempt to lower the pressure—that is, whether we have simply imperfect elastic recoil with increased peripheral resistance, or whether we have broken cardiac compensation.

It may be interesting to describe the effect of the treatment. Each application will, in about fifteen minutes, produce about a 10 per cent lowering of the maximum arterial tension as measured by the sphygmomanometer. For instance, in a patient with a pressure of 220 mm the reading will be about 20 mm less at the end of treatment. The following day the reading will have returned to its normal height, and this will go on for several days until one day before treatment the reading will be about 200 mm, then about a 10 per cent reduction on this will be obtained, until after a time no further reduction is effected. This may be taken as the limit to which the pressure should be reduced. Charted, the falling pressure is somewhat similar to a falling temperature chart in typhoid fever. The patient should attend daily until his low level is reached, when he should have treatment at such intervals as will keep him at this low level. These intervals vary much in each patient.

A discussion of the way in which the electric current acts, or a description of the apparatus, would be out of place in this Section, but here we have to tread somewhat delicately. Allbutt says "Diathermy does not, as far as we know, counteract the direct cause or causes of the malady, but until we know the primary cause, we may be thankful to counteract the secondary."

I suggest, however, that the therapeutics of this current in lowering blood pressure are twofold: there are the general, or constitutional effects, as affecting metabolism, and the local effects on the vasomotor system. The general effects of the current as influencing metabolism have been demonstrated both clinically and chemically. There is a gain in physical and mental strength, and general improvement in the health, the symptoms of insomnia, palpitation, or anxious fears disappear. Chemically there is an increase of solids in the urine, and a similar increase has also been found on analysis of the perspiration. The improvement in general metabolism is probably largely due to the effect on the vasomotor system, whereby the arteries, becoming relaxed, permit of a more free circulation of the blood, and, if this one fact be granted, the beneficial effects of the current are easily explained. A subsidiary cause may be at work—namely, the thermic effect of the current. This is quite apparent to the patient, and it may be that it causes an increase of functional activity by which the elimination of the toxic materials is augmented.

Then there must be a benefit, too, from a temporary relaxation of the arterial tension. If a piece of elastic is put on a stretch by attaching it to a weight continuously, after a time that elastic will cease to possess the recoil properties of elastic. But if the weight be removed for a short period at frequent intervals the recoil property will be evident for a much longer period of time—that is, the failing of the recoil property will be delayed. The analogy is obvious, though its bearing is perhaps somewhat hypothetical.

It is not claimed that in electricity we have the—or, indeed, any—cure, but we do say that with patients presenting a certain group of symptoms associated with hyperpiesia we can rely upon electricity, properly administered, to do a great deal. In the pre-sclerotic state signs and symptoms may be vague. These may be giddiness, a heavy feeling or fullness in the head, headache, often intensified with the effort of mental concentration ("the sign of painful thought"), insomnia or drowsiness, a disinclination to work, and an inability to concentrate the attention, alternating perhaps with an irritability of temper or occasionally with a mild psychic exaltation with confusion of ideas, failure of memory, noises in the ear, migraine or neuralgia, general nervousness with anxiety, or a sense of impending evil impossible to define.

Here we have a condition in which medical diathermy can accomplish much, apart from relieving the symptoms, for which alone the patient will often be very grateful. We believe that the treatment will check the degenerative processes which are going on and will ward off inevitable consequences, such as cerebral haemorrhages, renal affections, and the myriad ills which follow in the train of arteriosclerosis. Though electricity, as I have said, may be no cure, yet, except in very advanced cases, it will keep a patient for years in a condition of safety, and, indeed, in a state of comparative comfort.

GENERAL DISCUSSION

Dr McCRAE (Philadelphia) said that to his mind the outstanding feature of hyperpiesia was the difficulties it presented. In youth they met with individuals with high blood pressure, in some cases this was certainly merely temporary, in others it was permanent. He suggested that Lord Dawson's case was really secondary to organic disease, and he raised the question as to whether all cases of permanently raised pressure were not due to organic disease. Some cases of variation in the blood pressure were certainly independent of the vasomotor centre. In obese children with high tension the blood pressure frequently returned to normal at puberty, and high tension at the menopause was possibly due to endocrine influence. He concluded by emphasizing that this was pre-eminently a subject for investigation by the general practitioner.

Dr W SALISBURY-SHARRE (London) said that his series of 500 cases consisted wholly of men in the seventh decade of life, nearly all were between 60 and 65. His question was not so much one of continued life, but of fitness for continued work and of reliability and safety therein. The records showed the average systolic pressure of the group to be in the immediate vicinity of 180 mm., and that safety and efficiency depended more upon the heart condition than (within fairly wide limits) upon the actual figure shown on the sphygmomanometer. The actual condition of cardiac stress needed careful examination and experience in the reading of an aggregate of small signs to estimate it efficiently.

Professor CAWADIAS (Athens) said that he regarded hyperpiesia as a syndrome, and it was necessary to recognize that in addition to a central hyperpiesis there was also a local hyperpiesis—for example, in the limbs or the heart. In considering the etiology he thought there were three main groups—toxic, nervous, and chemical.

Dr D A ALEXANDER (Chifton) cited the case of a patient as illustrative of the discovery in the course of general practice of hyperpiesis in the young. A woman, aged 27, had much ill health, assumed from the family history to be due to latent tuberculosis, an irregular erythema appeared on the limbs which did not conform to erythema nodosum. When adrenaline was about to be tried it was thought desirable first to take the blood pressure, which was found to be 240 mm. In arterial condition the patient followed her mother, who had nephritis, her father's arterial state was probably that of low pressure, since he died of tuberculosis. The patient's heart was not enlarged, a little albumin had appeared in the urine since abdominal pain was frequent and severe, menstruation was irregular, and emotion was probably a cause.

Dr STACEY WILSON (Birmingham) referred to the difficulty in the present state of knowledge of recognizing the cause of any particular case of high blood pressure, and illustrated the point by an experience he had in the First Birmingham War Hospital. Two young men of about 25 years of age were under his care, one of whom both had a blood pressure of over 140. In searching for a focus they were both found to have an apical dental abscess, from which a streptococcal auto-vaccine was prepared. In the one case the vaccine treatment had no influence what-

ever on the high blood pressure, and in the other it was clearly the cause of its reduction to normal after three months' treatment. In the second case it was found that although the vaccine apparently produced no local or constitutional reaction, it did influence the blood pressure during the first forty-eight hours. In the early weeks of the treatment it was liable to cause a definite rise of blood pressure if too full a dose was given, and later on a fall in the blood pressure was often clearly traceable to an injection of the vaccine. The case, therefore, showed the desirability of always watching the blood pressure for at least the first two days after an injection of vaccine had been given for high blood pressure. In searching for a cause of high blood pressure it had to be remembered that not only did faulty brain circulation call for it when due to atheromatous cerebral arteries, but that a not infrequent cause of it was an amount of atheroma of the coronary arteries, which made a normal blood supply to the heart not possible unless the blood pressure was materially raised.

In order that their somewhat scanty knowledge of the pathology of high blood pressure might be increased, Dr Wilson emphasized the desirability of not only using the sphygmomanometer more freely than appeared to be the case at the present time, but also of making a more thorough study of those cases where it was used. For many years past he had not only used the sphygmomanometer in most of his patients, whatever their ailment, but had also adopted the following routine method. First, observing and noting the range of movement of the needle of the aneroid from the point where it commenced to the point where the oscillation ceased. Secondly, noting the systolic pressure as estimated by the finger. Thirdly, noting the sound at the bend of the elbow with the stethoscope as regards (a) the pressure at which the sound was first heard and the pressure when it was lost, (b) the point where a moderately loud sound was first heard, and the point where it ceased, (c) the range through which the maximal loudness of the sound was audible. The study of the oscillation of the needle was of great value in determining the output of the heart, and a sudden drop in the range of oscillation might, in an acute case, show the onset of myocardial weakness many hours before any definite symptoms appeared.

The systolic pressure as judged by the finger was often different from that estimated by auscultation. Although when the circulation was normal the two estimations were approximately the same, there might be a difference of 20 or more millimetres of mercury between them in abnormal states of the circulation, sometimes the one being higher and in other cases the other. The clinical significance of these differences was often far from clear. The loudness of the sounds at the bend of the elbow, as well as the range of the loud sound, gave important information as to the mode in which the heart was beating. If this fuller study of the pulse by means of the sphygmomanometer were followed out where possible they would gain more knowledge of the heart's action in disease than they had at present.

Professor R J S McDOWALL (King's College, London) said that of recent years he had carried out a large number of experiments on the peripheral circulation in animals. He had been impressed by the fact that much of the apparent divergence of opinion of the various specialists could readily be correlated along simple physiological lines, which had been confirmed by actual experiment, and which went to support the conception that hyperpiesis was due to active contraction of the arterial muscle which, subsequently, as a physiological result of overaction, would hypertrophy and later tend to degenerate. Many observers had drawn attention to the thickening of the media. Lord Dawson had emphasized the importance of strain or striving in the production of high blood pressure. Physiologically high blood pressure occurred in exercise in order, no doubt, to ensure better distribution of the blood. But it began in anticipation of the exercise. Under civilized conditions such a setting of the organism to effort was not necessarily to be succeeded by effort, but it could be demonstrated experimentally that in such circumstances definite vaso-constriction took place. This could be demonstrated as a diminution in the volume of the limb or a

decrease in the skin resistance. Several speakers had spoken of the undoubted influence of toxins, but it was not necessary to assume that these were necessarily pressor substances. A toxin such as alcohol or histamine, which was a normal constituent of the intestine, although a capillary dilator and capable of bringing about shock if absorbed in large quantities, brought about constriction of arteries reflexly, as did haemorrhage. Here, then, was another example of straining on the part of the vasomotor centre, but in this instance to maintain arterial pressure in spite of capillary dilatation, and which tended to soak up the blood and allow the animal to bleed, as it were, into its own capillaries. As he had pointed out in a recent paper, there was actually a pressor reflex, by way of the vagi, called into operation. These toxic effects were, then, not so essentially different from the simple nervous strain cases as it at first sight might appear. Thus reflex action might readily be overdone, and might be sup-

plemented by direct action of substances—for example, histamine, which, although a capillary dilator, had a definite constrictor action, as shown by Dale, on all smooth muscle. They knew that all reflexes, if continued, tended to become more active. He considered that the often rapid recovery in individuals suffering from hyperpnea, and the intermittency which was often observed, supported the conception that the condition was due to muscular contraction. Lord Dawson appeared to have summed up the matter when he stated that hyperpnea was in its first stage a physiological mechanism "gone mad." From physiological evidence the mechanism which was upset was that which was normally responsible for the raising of blood pressure in anticipation of exercise or the maintaining of it in blood loss. At first the condition might be temporary, but later, when degeneration or extensive hypertrophy set in, the high blood pressure would become permanent.

A Lecture

ON

RESPIRATION IN ANAESTHESIA.

CONTROL BY CARBON DIOXIDE.*

BY

YANDELL HENDERSON, PH.D.,
PROFESSOR OF APPLIED PHYSIOLOGY, YALE UNIVERSITY

To understand, to predict, to control these are the objects of all scientific investigation. The last and greatest is control, but unless we have first attained an understanding of the nature and working of basic phenomena, prediction is inaccurate or impossible, and control is incomplete and unreliable. Such, I take it, is always the relation of applied science to pure science.

Anaesthesia is one of the most beneficent of the applications of science, and one of the greatest achievements of modern medicine. Perhaps if we took all other drugs and weighed them in the scales of usefulness against the anaesthetics, the balance would incline in favour of the anaesthetics. We should expect, therefore, that the fundamental phenomena of anaesthesia would have been very thoroughly explored, and that much inventive ingenuity would have been applied to the utilization of fundamental principles. In fact, however, the art of anaesthesia as we have it to-day is founded on little more fundamental knowledge than that certain substances produce unconsciousness, and until quite recent years anaesthetists have been content with an extreme crudity of technique. It is probable that 90 per cent, perhaps even 99 per cent, of all anaesthetics in the world are still administered by dipping the liquid anaesthetic on to a towel or into a cone or on a few layers of gauze, the anaesthetist trusts to the heat of the atmosphere to volatilize the liquid into a gaseous form.

It is one of the first principles of anaesthesia that it is only when the liquid anaesthetic is vaporized and inhaled in gaseous form that it can be absorbed from the lungs into the blood and produce its desired effects. It is another first principle that the depth of anaesthesia should be maintained as nearly uniform as possible, and yet another principle that this depth should be attained as quickly as possible, and that the first stage, the stage of excitement, should be made as short as possible. But, in fact, the fulfilment of these requirements is made as difficult as possible by the crudity of the method of volatilization employed. The conditions are those of an essentially unstable equilibrium. Stable equilibrium would require, in respect to anaesthesia, that the condition should be such as would automatically tend to increase the concentration of ether inhaled whenever the patient tends to come out, and, contrariwise, to decrease the concentration whenever the patient is sunk too deeply under the influence of the drug. In fact, however, as soon as the patient emerges

to any extent, the volume of his breathing increases, and under the drop method more of the anaesthetic is blown away by each expiration. Thus the anaesthesia tends to be still further decreased. Contrariwise, when the patient is deeply anaesthetized, the volume of breathing grows less, and the tendency is for a more concentrated vapour to be inhaled. The latter tendency is met by the watchful anaesthetist decreasing the rate at which the anaesthetic is dripped upon the mask. But it is far more difficult to meet the situation when the patient is excited and struggling. Sometimes, during recurring periods of excitement, it seems as if the more liquid that is poured upon the mask the more it becomes chilled and frosted, the less the volatilization therefore, and the greater the difficulty of getting the patient under again. By such recurring periods of excitement, alternating with periods of unduly profound anaesthetic coma, the vitality of the patient is depleted to an extent equalled only by a severe haemorrhage. The risk of failure of respiration or circulation is increased, and a prolonged period of post-anaesthetic prostration and slow recovery is rendered inevitable. There is probably also an increased liability to a subsequent pneumonia.

I am aware that this picture is somewhat highly coloured, although I insist not too highly. I rather expect that one or more skilful and conservative anaesthetists will take up the cudgels and reply "Nothing of that sort occurs as I conduct anaesthesia." In my own country, at least, such remarks as I have here made have called forth this rejoinder. But my answer is ready. The fact that these conditions do not occur in your cases is due, my dear sir, or madam, to the great skill which you have acquired as the result of natural aptitude and unflagging care, and not to the inherent adaptation of a mask and dripping bottle to the production of a uniform or easily controllable mixture of vapour in air.

Perhaps I ought to confess here that I am not an anaesthetist by profession, but merely a physiologist with a special interest in respiration and in gases and other volatile substances, including the anaesthetics, of course, which enter the body through respiration. For twenty years I specialized in bird anaesthesia by the drop method. Out of a hundred or more cases a year I saw a mortality early in anaesthesia running usually around 30 per cent, and sometimes higher. I was then teaching physiology, and I felt that medical students could not have a more valuable experience than to have undergone the trouble and anxiety of an anaesthetist with a bad case, and that even to have had a "death on the table" was very instructive for them. Of course, I reprimanded them and sent them away in disgrace whenever a fatality occurred, saying to them "It is not allowable for you to report, I have killed that patient, give me another!" Let me explain, however, that the patients in question were not cats or occasionally dogs, which were intended for experiments on blood pressure. It seemed to me that it was well worth while for these future medical men to have an experiment delayed and to have to buy another animal, for the sake

of seeing how disastrously the vital mechanism may be affected by badly administered anaesthesia.

While those young men thus learned the elements of anaesthesia I utilized the opportunity to study anaesthetists. I am convinced that they made no errors that are not inherent in the drop method, or that are not made to some extent by all who use it. They merely made these errors much more frequently, more acutely, and on subjects which, being smaller and more excitable than human patients, are more readily and more obviously affected deleteriously.

Importance of Control of Breathing

What, then, is it that an unskilful anaesthetist does? Or, contrariwise, what are the errors which the skilled anaesthetist instinctively avoids? To put the matter in a single short statement, which I shall spend the remainder of this hour in elaborating, the whole difference between good and evil in anaesthesia lies in this: the capable anaesthetist with suitable apparatus and technique controls respiration to his purpose, or adapts his administration to the patient's respiration. The incapable anaesthetist, on the contrary, is constantly struggling with a respiration over which he has neither intelligent nor instinctive control; he is like the nervous driver of a horse, or, if he is more up to date, of a motor car which alternately runs away with him and stalls. What I shall here say applies particularly to the use and effects of ether, for chloroform, formerly extensively used in America, has, I am glad to say, been almost entirely discarded.

Respiration is a function of great variability. Its rate may vary from four or five times a minute to twenty or thirty or more. The volume of air breathed may vary from 5 litres a minute to 30 or 50 or more. It is unfortunate that respiration is usually thought of in terms of rate. The really important quantity is the volume of air breathed in a minute. This is particularly true with relation to anaesthesia, for the quantity of the drug that the patient receives is the product of the volume of air breathed and of the concentration of the vapour mixed with the inhaled air. Let us say no more of the rate of breathing therefore, but let us fix our attention on the volume a minute.

The significance and relations of the volume of air that a man breathes were first clearly grasped and explained by Haldane.¹ The interpretation which he gave of this matter has been one of the most important contributions that modern physiology has made to the science and art of medicine. It has been the foundation of the developments in many important clinical fields, among others that of anaesthesia. It has been particularly appreciated, and its originator honoured, in America. In fact, in delivering this lecture, I come as one of Haldane's disciples to preach an application of his doctrine in the land of the prophet of modern science who is its author.

The principle is simple. Carbon dioxide is produced in the body by the same process by which oxygen is consumed. The supply of oxygen has relatively little immediate influence upon respiration. The administration of pure oxygen gas never acts as a stimulant. Carbon dioxide, on the contrary, is the normal stimulant and regulator of breathing. The amount, or, more exactly, the pressure, of carbon dioxide in the air in the lungs, and thus in the arterial blood flowing from the lungs, acts upon the respiratory centre so precisely that in normal life the volume of air breathed is kept in almost exact proportion to the amount of carbon dioxide. Even during the tenfold variation of carbon dioxide production during bodily rest and in vigorous muscular work, the proportion of respiration to the amount of its gaseous stimulus is maintained. In other words, the lungs are automatically ventilated so that the air which they contain has, under all normal conditions, a content of a little more than 5 per cent of carbon dioxide. This concentration of carbon dioxide is also one of the prime factors in the acid-base balance of the blood and tissues. It is itself the chief acid in this balance, and it controls indirectly, but effectively, the amount of the alkali in use in the blood.

Suppose now that a nervous patient is anaesthetized.

His anxiety has caused overbreathing and an abnormal depletion of the carbon dioxide in his lungs and blood, the condition of *respiria*, and other disturbances of function. Suppose that the first stage of anaesthesia is prolonged, a stage in which the exciting effect of an insufficient concentration of anaesthetic in the blood often causes excessive breathing and further depletion of the body's normal store of carbon dioxide. I am speaking now particularly of ether administered by the drop method. Finally a sufficient amount of the drug is administered to produce full anaesthesia. The sensitiveness of the respiratory centre is thereby reduced to normal, or, if the anaesthesia is profound, it is reduced far below normal. Respiration may then fail temporarily, and it is to be noted that this failure is not merely the result of what the anaesthetist has done in the minute preceding. It is rather the resultant of all that the patient has been through up to this time. The excessive breathing has reduced the carbon dioxide and has thus decreased the normal stimulus for respiration. It has finally caused an excessive inhalation of the anaesthetic vapour, and thus reduced the sensitiveness of the respiratory centre much below normal. There is therefore a simultaneous decrease both of the stimulus and of the sensitivity of the centre. Respiration inevitably stops, and with it ceases the supply of oxygen to the blood, and so to the brain. Thus to *respiria* is added *anoxaemia*. If respiration is restored, the *anoxaemia* leads to another period of excessive breathing, and so to an intensification of *respiria*—a vicious circle of increasing velocity.

The Control of Anaesthesia

The practical problems of anaesthesia are uniformity of administration, rapid induction and termination, prevention of *respiria* and *anoxaemia*, and preservation of the patient's vitality generally. These problems have been attacked with marked success in America during the past decade. Our anaesthetists have asserted the importance of their work and have brought our surgeons to realize, as they formerly did not, that the anaesthetist plays a part, for good or ill, in the outcome of every major operation, second only to that of the surgeon himself. From being a matter of dead routine, anaesthesia has become a field of active study and progress. The national and local associations of anaesthetists hold meetings and publish discussions and researches which testify to the live interest and vigorous development in their field. But the particular aspect of this growth to which I wish to call attention is the invention of apparatus for administering the various forms and combinations of anaesthetics.

These apparatus enable the anaesthetist to administer nitrous oxide, ether, ethylene, sometimes even acetone, and other new anaesthetics, in any sequence or combination, with oxygen pure or combined with any percentage of carbon dioxide. It is particularly noteworthy that such provision is made for volatilizing ether that it is administered as a vapour. There is also in nearly all such apparatus a rebreathing bag or bags, and various valves and other devices for estimating the volume of the flow of the gases in and out of the bag, and also the volume of the patient's breathing. Some of these apparatus are, indeed, quite unnecessarily or even appallingly complex, but they give the anaesthetist a far greater control over conditions than he has ever had before. Nearly every prominent anaesthetist has a special apparatus which he has devised, and the clinical journals are full of advertisements of these devices, thus testifying to the extent to which their use has already grown.

Only the main features common to most of these apparatus and approved by almost universal experience concern us here. The primary features, in my opinion, are the rebreathing bag and such accessories as a cylinder of compressed oxygen, another of carbon dioxide, pure or diluted with oxygen, and the valves for their control. As regards this bag, experience has shown, in confirmation of theory, that nothing contributes so much to uniformity of anaesthesia as properly adjusted rebreathing. Our lungs are themselves a rebreathing apparatus, especially fitted to prevent fresh atmospheric air from coming in contact with the blood as it flows through the pulmonary vessels.

Suppose that the lungs had only the capacity of the breath and were emptied by each expiration, then at each inspiration the gaseous contents of the lungs would be virtually atmospheric air, and the blood would be momentarily greatly over-oxygenated. Similarly by the end of each expiration the air in the lungs would be so vitiated that the blood would be inadequately oxygenated. The faces of our friends would go blue and pink a dozen times a minute. Instead of this truly alarming spectacle, Nature has arranged that the lungs constantly contain 3 to 5 litres or more of air, of which only about a tenth is thrown off at each respiratory tide. This fraction is replaced by the same quantity of fresh air, which is immediately mixed with the stationary air. Accordingly, in the successive phases of each breath, the composition of the air in the lungs normally varies so little that the oxygen and carbon dioxide rise and fall by only two or three tenths of 1 per cent.

By following Nature in this regard, anaesthetists have found that the addition of a rebreathing bag of 4 or 5 litres to the volume of the stationary air of the lungs is advantageous. The total contents of lungs and bags are thus about 8 litres, and the variations in the composition of the air are reduced to half what they would be in the lungs alone. This is true even when a volume equal to the whole volume of the tidal air escapes from the bag at each expiration, and is replaced by fresh air or oxygen. The equalizing and conserving effects are even more marked when the volume discharged and replaced is less than the tidal volume by a third, a half, or even two-thirds.

This is the main point in the now well established principle of enlarging the stationary air of the lungs by the addition of a rebreathing bag. It requires, however, that oxygen from a cylinder attached to the apparatus shall be fed into the bag instead of merely atmospheric air. In order to be managed in the best manner, the apparatus must have a sufficiently accurate device for measuring the flow of oxygen, so that the anaesthetist knows within a small fraction of a litre how much oxygen he is feeding in each minute. The apparatus should also afford at a glance a quite approximate indication of the volume of the breath, and thus, from the volume and rate, a close estimate of the respiratory volume a minute. Furthermore, there must be, and on all the apparatus that I have seen lately there is, some arrangement for volatilizing ether, so that the anaesthetist can feed the vapour to the mask over the patient's face, or into the rebreathing bag, instead of handling merely a liquid, which may or may not volatilize completely and immediately. Such a device is essentially similar to the carburettor in which petrol is volatilized in an automobile—a fact full of practical suggestion for those with a turn for invention or adaptation.

Use of Carbon Dioxide with Anaesthesia

Finally, there is a feature in an increasing number of these apparatuses, and in the technique employed by an increasing number of the most skilful and intelligent anaesthetists, to which I wish especially to direct attention. It is a cylinder of a mixture of oxygen and carbon dioxide. The amount of carbon dioxide, the percentage added to oxygen, is still variable. On physiological grounds and in order to play safe, I first recommended about 5 per cent of carbon dioxide in 95 to 99 per cent of oxygen.² But one anaesthetist after another has used stronger and stronger mixtures with increasing advantage, until now some of the most competent tell me that 25 per cent carbon dioxide in 75 per cent oxygen is the mixture which affords them the most perfect control of respiration. Of course, it is not used straight, but is added to air or to oxygen from another cylinder. It then allows any degree of stimulation, and in fact it enables the anaesthetist to exercise an absolute control of the patient's breathing. Thus at the initiation of anaesthesia before nitrous oxide, or ethylene, or ether vapour is turned on, full deep breathing may be induced. Then the anaesthetic is added, and full anaesthesia is induced almost instantaneously. The stage of excitement is virtually eliminated. During anaesthesia the breathing can be allowed to decrease as it does under the full effects of ether and ethylene, or it can be increased by throwing into the breathing bag a moderate amount of the carbon

dioxide-oxygen mixture. Finally, at the termination of the anaesthesia, the supply of anaesthetic is shut off, the breathing bag is emptied or disconnected, and by mixing some of the carbon dioxide-oxygen with the air which the patient inhales vigorous breathing is stimulated for a few minutes, and the anaesthetic is quickly ventilated out of the patient's blood. Consciousness returns with extraordinary rapidity, although enough of the anaesthetic still remains in out-of-the-way parts of the body to induce the patient to sink into a condition approximating normal sleep, after removal from the operating table to his bed.

The principal advantages of modern anaesthetic apparatus over the mask and dropping bottle are, then, as follows:

- (1) Ether is fully vaporized before it is administered. This is advantageous, not only for the reasons already stated, but also because the deleterious cooling effect of ether, when vaporized close to the patient's face, is thus eliminated.
- (2) The use of rebreathing apparatus affords a far more uniform concentration of the anaesthetic vapour than is attainable in any other way. The contents of the bag should be so enriched with oxygen that its supply and concentration are always equivalent, or more than equivalent, to that in atmospheric air. The rate at which the contents of the bag are renewed is then adjusted to keep the pressure of carbon dioxide at that concentration which will afford the amount of respiration desired.
- (3) The use of carbon dioxide mixed with air or with oxygen furnishes the anaesthetist with the means of dominating respiration and of using this function for the purposes of rapid induction, smooth administration, and rapid termination of anaesthesia. He is no longer under the necessity of struggling with unsteady breathing, while the vitality of the patient melts away under his hands. Nothing in my observation is more striking than the differences in the appearances of patients anaesthetized in two different ways. Those of one group were etherized by the open drop method in the usual fashion, and were then left to hours of subnormal breathing, cyanosis, nausea, acrimonia, and anoxaemia. In contrast to these conditions are the rapidity of the return of normal functions in patients who have had uniform anaesthesia, rapid elimination of the anaesthetic, and a restoration of their store of carbon dioxide sufficient to ensure normal breathing, and therefore a normal oxygenation of the blood, during the hour following anaesthesia.

Other Uses of Carbon Dioxide

The use of carbon dioxide as a means of controlling respiration is not confined to the field of anaesthesia. It applies equally well to other scarcely less important problems. Several anaesthetists of my acquaintance have told me of their success in overcoming the asphyxia of the newborn by a brief inhalation from a cylinder of mixed oxygen and carbon dioxide. The last case that I learned of was that of a baby which persistently refused to breathe spontaneously until its lungs were inflated a few times with 25 per cent carbon dioxide and 75 per cent oxygen. Then it started breathing on its own account. In fact, it could not very well do otherwise, if it had any respiratory centre at all. At the last report, some days later, it was breathing as if it intended to continue for a full life term of three-score years and ten.

Another very practical use to which the inhalation of carbon dioxide has been put is in the treatment of alcoholic intoxication. This is a matter both of benefit to the patient and of a very large saving of expense in a large city hospital. Alcohol of all varieties is volatile. Common experience and the sense of smell teach us that even in quiet breathing some of it may be exhaled in the breath. Ethyl alcohol is burned in the body to a certain extent but methyl alcohol, which now is contained in some cheap liquors, at least in America, is not burned. It is very slowly excreted, and if it accumulates in the body it is extremely poisonous, causing optic atrophy and thus many cases of permanent blindness. Such patients may occupy hospital beds and be a source of expense for weeks. On the other hand, it is found that by means of simple and inexpensive apparatus for administering carbon dioxide mixed with air, which is also very cheap, even a comatose alcoholic may be made to ventilate the alcohol out of his blood through

his lungs in the course of an hour or so. He can then be discharged from the hospital sober and well the next morning.

Still another and even more important use of carbon dioxide as a stimulant for respiration has been developed in connexion with carbon monoxide asphyxiation. Such cases occur frequently in every city where the amount of carbon monoxide in the public gas supply is allowed to rise above the minimal amount. They occur also frequently among the men in the city fire brigade, for the smoke from a burning building usually contains considerable amounts of carbon monoxide. Carbon monoxide asphyxiation is best known perhaps as the result of explosions and fires in coal mines. In the blood of the victim the haemoglobin is so far combined with carbon monoxide that its capacity to transport oxygen is seriously diminished. As Haldane showed, oxygen will drive the carbon monoxide out again and restore the normality of the blood. But as Haggard and I have shown, in addition, an asphyxiated man breathes so poorly that oxygen is not adequately inhaled when administered. Accordingly we have introduced very widely in America, and to some extent on the continent of Europe also, the use of oxygen to which 5 per cent of carbon dioxide has been added. This mixture must be administered with a properly devised inhaler, one which allows a very large volume of breathing, in order to produce the best results. The great increase of breathing, which the carbon dioxide in the mixture stimulates, causes the blood in the lungs to be flushed and flooded with oxygen, by which the carbon monoxide is rapidly displaced.²

This matter may seem somewhat apart from anaesthesia. But there is one point in connexion with it which has a special bearing here. It is the fact that persons primarily asphyxiated, and left to recover without such treatment, very frequently develop pneumonia. In fact, in the past a considerable percentage of all deaths, primarily due to asphyxiation, have been the immediate consequence of a secondary pneumonia. On the other hand, patients who soon after asphyxiation have been treated with the oxygen and carbon dioxide mixture not only recover rapidly from the asphyxiation, but are also relieved of the danger of pneumonia. There is considerable ground for the claim that a similar elimination of post-anaesthetic pneumonia is afforded by the use of oxygen and carbon dioxide at the end of each surgical operation.

The Absorption, Distribution, and Elimination of Ether

So much for the application of the principles of respiration to the clinical side of our subject. Now let us consider some of the results that have come from recent investigations in the laboratory, but which are not yet fully realized by anaesthetists. The work to which I wish particularly to refer was carried out a couple of years ago in my laboratory at Yale University by my associate, Dr H. W. Haggard.⁴ It dealt with the principles underlying the absorption, distribution, and elimination of ethyl ether. It has, however, a wider application even than this broad field, for the same principles apply to any gas or vapour whatever that may be inhaled and that is taken up by the blood and by the tissues of the body in simple solution. A similar study of the absorption, distribution, and elimination of nitrogen was made some years ago by Haldane, Borecott, and Damant⁵ in connexion with their important investigation on the prevention of compressed air illness.

The determining characteristic of each gas or vapour is its solubility, for the coefficient of solubility determines the distribution, or equilibrium, between the vapour in the lungs and the solution of the substance in the blood flowing through the lungs. Secondly, and much more slowly, it determines the concentration in the tissues. The more soluble the substance the more the body will finally take up, but the longer the time required to reach saturation. Both the amount held in the blood and in the tissues at the point of saturation and the rate of absorption are directly proportional to the concentration in the inhaled air. For any one gas or vapour such as ether the time is the same for all concentrations to reach the full saturation corresponding to that concentration, or any given percentage of that saturation. In regard to absolute amounts,

therefore, the initial rate of absorption when a high concentration is inhaled is proportionally greater than when the concentration in the air inspired is low.

The solubility, or coefficient of distribution between blood and air in the lungs, is a factor also in the elimination of a gas or vapour that has been absorbed. It is of fundamental importance both for the induction and for the termination of anaesthesia.

The One Essential Condition for Anaesthesia

Haggard's experiments have demonstrated that there is at all times equilibrium in respect to ether between the air of the lungs and the arterial blood. Furthermore, the circulation through the central nervous system, and especially the brain, is so large that the concentration of ether in the nerve centres becomes almost immediately the same as that in the arterial blood. This uniformity of the pressure of ether in the lungs, blood, and brain is similar to that which we know from the work of Haldane and his collaborators holds true of carbon dioxide. The pressures of carbon dioxide in the lungs and in the brain are equal and so, too, of ether.

These are facts not only of great theoretical interest but of direct practical importance. Haggard has demonstrated that the condition of surgical anaesthesia depends on nothing else but the concentration of the anaesthetic in the central nervous system. The degree of saturation of the rest of the body has no direct influence on anaesthesia. Formerly we had supposed—and certainly superficial appearances during the induction of anaesthesia suggest—that a certain time is required to saturate the body up to the point at which the state of anaesthesia occurs. This appearance is fallacious. We can, in fact, calculate the length of time that it would take for the body to become even half saturated. It would be about two and a half hours.

Now that we know that the sole condition for full surgical anaesthesia is the concentration of ether in the brain, and that this is immediately determined by the concentration in the lungs and blood, we see that theoretically it is possible to carry a man from full normal consciousness clear into full surgical anaesthesia in a period of not more than two or three minutes. This is not only theoretically possible, it is actually practised, and it is of great advantage to the patient.

The coefficient of distribution of ether between the vapour phase at body temperature and its solution in blood is 15. This means that there is equilibrium when a certain volume of the blood contains 15 times as much ether by weight as an equal volume of pulmonary air. The anaesthetic tension of ether is 3.7 to 4 per cent of an atmosphere, which comes to about 12 grams of ether per litre of blood. The anaesthetic concentration is probably the same for everyone even for the most recalcitrant old alcoholic case. The reactions prior to attainment of anaesthesia, and the amount of difficulty in administration which they produce, are the real variables as between different patients, and not the concentration at the point of full anaesthesia.

Technique for Rapid Induction of Anaesthesia

The practical problem facing us, then, is that of how other can be volatilized and the vapour passed into the lungs rapidly enough to raise the concentration in the arterial blood immediately to the full anaesthetic amount. Obviously some device far more efficient than a mask or cone and dropping bottle is needed to vaporize the amount of ether needed. But that is only the mechanical side of the problem. Owing to the high solubility of ether in blood fifteen out of every sixteen parts of ether drawn into the lungs at first pass into the blood. Haggard and I have recently shown that the circulation in a normal man is much larger than has generally been believed heretofore. About the same volume of blood flows through the lungs in a minute even during rest, as the volume of air normally breathed in that state. Owing to the dead space (the mouth, trachea, and bronchi) only two thirds of the air breathed reach the lungs. So it follows that, in order to induce full anaesthesia within two or three minutes with no more than normal breathing, the concentration of the ether vapour inhaled would have to be extremely high.

Extremely high concentrations of ether vapour have, in fact, frequently been used, especially in Germany, during the initiation of anaesthesia. But such concentrations have an irritating effect upon the lungs, especially when the vapour is very cold, and are objectionable on other grounds also. So the problem of rapid, safe, harmless induction resolves itself into this: How can a large amount of ether, 6 or 8 grams a minute, be introduced into the pulmonary blood? Or, to restate the question: How can 9 to 12 grams of ether a minute be introduced as vapour into the inspired air without increasing the concentration of ether in this air to appreciably more than 7 or 8, or at most 10, per cent vapour?

These questions almost answer themselves. Obviously, to introduce a large amount at a comparatively low concentration is possible in one way only—that is, by means of a large volume of breathing. The principles to which I have already referred, controlling the absorption of a gas or vapour, teach us that any relatively slightly soluble volatile substance is absorbed, and eliminated again, nearly in proportion to the circulation—that is, to the volume of blood flowing through the lungs per minute. On the other hand, these principles demonstrate that a quite soluble vapour, such as that of ether, is absorbed almost in proportion to the volume of air breathed, or, more exactly, to the pulmonary ventilation. Thus if fifteen sixteenths of all the ether vapour drawn into the lungs at first are taken up by the blood, it is only necessary to increase the volume of breathing so that the necessary absolute amount of ether will be drawn into the lungs in a sufficiently large volume of air. Thus a large absorption is effected without allowing the concentration in unit volume of the air to rise high enough to irritate the passages and chambers of the lungs. Thus we are again led to see the advantage of stimulating respiration, by means of carbon dioxide, up to several times the ordinary resting volume, and then running in a sufficient concentration of fully vaporized ether to produce in the shortest possible time the concentration of ether in the blood, and thus in the brain, necessary for full anaesthesia.

Relation of Respiration to Blood Alkali

One of the topics which has excited the greatest interest during recent years in the borderland between physiology and clinical medicine has been the balance of acids and bases in the blood and other fluids of the body. The resultant of this balance is the so-called hydrogen ion concentration. Modern chemistry teaches that this is the essential element in what we formerly called acidity, and that it is a factor in most of the reactions of substances in solution. It has become clear that the concentration of hydrogen ions in the blood has a normal value, and that the automatic processes of the body tend to adjust it to this value. It is thus another of the vital constants, such as body temperature, arterial pressure, the amount of salt and of sugar in the blood, and the other conditions whose uniformity constitutes health. From the standpoint of physiology, disease may be defined as a disturbance, or a perversion to an abnormal value, of one or more of these normal vital constants.

The two chief factors in the acid-base equilibrium of the blood are (1) the amount of alkali in use in the blood, which is chiefly the sodium bicarbonate of the plasma, and (2) the pressure of carbon dioxide maintained in the blood by respiration, and thus the amount of carbonic acid in simple solution. As is well known, this equilibrium tends to be disturbed in anaesthesia. The blood alkali after a prolonged and difficult anaesthesia may be reduced to an extent which is recognized as a serious departure from the normal for health. It is the condition now, rather loosely, called acidosis.

The term "acidosis" has long been applied to such conditions as occur in acute diabetes, and the post-anaesthetic state has obvious points of similarity to diabetic coma. The word "acidosis" suggests that the chemical condition is due to poisoning by acids resulting from disturbed metabolism. We are coming to realize that this conception is far too simple and too crassly mechanistic.

But it still exerts a great influence, and the hold which it has upon medical thought was greatly strengthened by the introduction of the term and conception "alkaline reserve" to signify the blood alkali, and particularly the sodium bicarbonate of the plasma. Thus, when it was found that in conditions of so-called "acidosis" the blood alkali was below normal, this fact seemed to be a direct demonstration of the idea that the alkali had merely been partially neutralized by acids.

I have recently shown⁷ that there are very serious discrepancies in this general conception. For instance, the real alkaline reserve of the blood is now known to be composed to only a quite small extent of the plasma bicarbonate, it is to a much greater extent the haemoglobin alkali of the corpuscles. Thus the mere addition of a moderate amount of acid to blood does not reduce the plasma alkali correspondingly. Even when an amount of lactic or other strong acid is found in the blood corresponding to the lowering of the bicarbonate, this fact does not justify the conclusion that the lowering is due to neutralization by the acid. Most of the acid is neutralized by alkali from the corpuscles, and some additional factor must be looked for to explain the greater part of the lowering of the plasma alkali. Such a factor was found by Haggard and myself in respiration.⁸ When the lungs of an animal were ventilated excessively by means of artificial respiration an excessive amount of carbon dioxide was removed from the blood. This removal would leave the blood alkali in relative excess, and we found that a compensatory decrease occurred. Presumably this was due to the passage of alkali from the blood into the tissues. Similarly, when we depicted respiration by means of morphone, and then administered an inhalation of air to which 8 or 10 per cent of carbon dioxide was added, we found that the carbonic acid of the blood was at first raised out of balance to the alkali. But under these conditions physiological readjustment developed, so that a considerably increased amount of alkali was, as we expressed it, "called into the blood" in the course of half an hour. These and similar experiments reveal to a very considerable extent the normal mode of control of the amount of alkali in use in the blood. The living body is not merely a beaker containing a slightly alkaline solution, in which the amount of alkali is determined by the amount of acid that is spilled into it, or by the excess or base in the food. On the contrary, this factor in the vital economy is regulated physiologically, and in this regulation respiration is one of the prime elements. When respiration is excessive, the pressure of carbon dioxide in the blood is lowered and alkali tends to pass out of the blood, when respiration is depressed, the pressure of carbon dioxide in the blood is increased and tends to call more alkali into the blood.

With this conception to justify us, Haggard and I turned to the study of the blood alkali in patients following prolonged anaesthesia. We found, in agreement with others, that the amount was often much below normal, and that it tended to rise only slowly, and in the course of many hours. We then tried the effects of inhalations of air and 8 or 10 per cent of carbon dioxide, or whatever concentration was necessary to produce a distinct effect upon the visible physical condition of the patient. In all such cases we obtained, not only a rapid elimination of the anaesthetic and a return of a full normal circulation, together with relief of cyanosis and recovery of a pink skin colour, but also a rapid return of alkali to the blood, so that in the course of half an hour this element in the balance was back at very nearly its normal value.

For a considerable time we met with criticism and opposition, especially from biochemists, who alleged that a low blood alkali is a definite indication of "acidosis"—that is, of an excess of acids in the blood, and that the administration of carbon dioxide was therefore absolutely contraindicated. Then view of the matter was that the post-anaesthetic state is similar to that following an asphyxia, and that the condition of the blood may be regarded as essentially an "asphyxial acidosis." I accept these premises, but not the conclusion. Facts, both experimental and clinical demonstrate that carbon dioxide, both after

anaesthesia and after asphyxia, instead of exacerbating the condition called "acidosis," tends to relieve it.

I am inclined to the view that the lowering of the blood alkali by anaesthesia is to be explained as a secondary result of acapnia, the excessive blowing off of carbon dioxide, rather than as due to an excessive production of acids. In fact, I doubt whether such a condition, as the term "asphyxial acidosis" implies, occurs even in poisons overcome by carbon monoxide. The orthodox fundamental conception implied by this term is probably erroneous. But I prefer to recognize that in this whole field of tissue respiration we have still a great deal to learn. I have tried to avoid the error of overthrowing a false conception by substituting for it another which might ultimately prove equally misleading. It would be a mistake to overemphasize theoretically the direct benefit of an increased pressure of carbon dioxide in the blood and tissues. Acapnia is not the whole story. Oxygen is also a factor in the vital economy, and the inhalation of carbon dioxide, by improving respiration, causes both a greatly improved oxygenation of the blood and a greater readiness in the blood to give off oxygen to the tissues.

All theorizing aside, I take my stand on the absolutely demonstrable fact that inhalation of air or oxygen to which a considerable percentage of carbon dioxide has been added is of very great benefit, in fact, is usually brilliant in its effects, alike after a prolonged anaesthesia and after asphyxiation.

Haemorrhage and Respiration

Closely related to the disturbances and hazards involved in anaesthesia are the effects of haemorrhage. The parts played by anaesthesia and by haemorrhage in the depression of vitality, or more extremely in the degree of shock, are so much alike that it is often difficult to estimate their relative contributions. A few words on haemorrhage may therefore be in order, even at the end of a paper into which I fear too many topics have already been introduced.

What is haemorrhage physiologically? In other words, what is the intermediate factor through which a decrease of blood volume leads to shock and death? Physiologists would, until recently, have answered unquestioningly and unreservedly that this factor is lowered arterial pressure. Thus the chain of causation would run: loss of blood, decreased blood volume, lowered arterial pressure, shock. During the war this conception was developed practically and therapeutically by one of the most eminent of British physiologists, the late Professor Sir W. M. Bayliss.² He introduced the so-called gum saline solution for purposes of infusion, because he found that this solution does not pass out of the blood vessels as normal saline alone does. It replaces the lost blood with a medium by which arterial pressure is quite well restored and maintained.

It was later shown by a number of investigators, especially in America, that gum saline solution has distinct toxic properties, and that it is not a satisfactory substitute for a transfusion of blood from a donor. But that matter is apart from the point to which I wish to call your attention, and which is as follows. Investigations in my laboratory,³ also during the war, led to quite a different conception of haemorrhage. According to this view, haemorrhage is essentially asphyxia. It is the loss of red blood corpuscles which is the critical initial factor. In consequence of the loss of corpuscles the capacity of the blood is invalidated in at least three respects: (1) its capacity to transport oxygen from the lungs to the tissues, (2) its capacity to transport carbon dioxide from the tissues to the lungs, and (3) its capacity to maintain the normal acid-base balance in the blood. These are the three functions which we now recognize that the haemoglobin of the corpuscles normally enables the blood to perform. Accordingly, a series of symptoms and conditions develop after haemorrhage closely analogous to those occurring under carbon monoxide asphyxia. Excessive breathing, induced by oxygen deficiency in the brain and tissues and culminating in air hunger, is a significant phenomenon. We found, in fact, that quite soon after a large haemorrhage in an animal we

could foretell the final outcome by means of two measurements of the volume of breathing spaced about an hour apart. If the volume of breathing held steady, recovery almost invariably followed; if, on the contrary, it increased progressively, there was almost invariably a fatal termination.

For the anaesthetist who is asked to pilot a patient through an operation after a haemorrhage of unknown amount, a measurement of the volume of breathing would, I believe, afford an indication of the risk more significant than the arterial pressure. It would tell him whether he should first insist on a transfusion of blood. It would warn him of the special need to keep up the oxygen supply and to avoid both acapnia and anoxaemia with the utmost care. In fact, if the conception is correct that haemorrhage is essentially a form of asphyxia, the observation and control of respiration which, as I have here tried to show, are essential to skilful anaesthesia should be extended so as to afford an understanding and a means of counteracting to a large extent the effects of haemorrhage as well.

SUMMARY AND CONCLUSIONS

The essentials of good anaesthesia are rapid induction, uniform concentration of vapour, and rapid termination. In the drop method of administration the vaporization of a liquid anaesthetic is often irregular. A more reliable and more uniform method of producing the vapour in proper concentration in air is desirable and is afforded by many of the forms of apparatus introduced recently.

The use of a controllable amount of rebreathing is also advantageous in the maintenance of a nearly uniform concentration of the anaesthetic vapour and of oxygen and carbon dioxide.

An almost complete control of respiration is afforded the anaesthetist by the use of carbon dioxide mixed with oxygen. By its use rapid induction and termination of anaesthesia and any desired volume of breathing and depth of anaesthesia are at his command.

It is not the amount of anaesthetic in the body which determines anaesthesia, but that in the nervous system. The amount in the nervous system at all times follows closely the concentration in the arterial blood, and the concentration in the arterial blood is in turn determined by the volume of the breathing and the concentration of the anaesthetic vapour in the air inhaled. Thus control of respiration is the essential element in the control of anaesthesia.

The use of carbon dioxide as the means of controlling respiration applies also to asphyxia of the newborn, alcoholic intoxication, carbon monoxide asphyxia, and related conditions.

The restoration of an approximately normal content of carbon dioxide in the lung air and in the blood and tissues of the body at the termination of anaesthesia probably tends strongly to prevent the development of a post-anaesthetic pneumonia. It is also a means of restoring a nearly normal acid-base balance in the blood.

Finally, the close similarity of haemorrhage to asphyxia renders it another of the elements whose effects are to be understood and controlled through the application of the principles of the physiology of respiration.

HAEMORRHAGE IN ASSOCIATION WITH PREGNANCY, LABOUR, AND THE PUERPERIUM*

BY

J W BRIDE, M D, B S Lond,

ASSISTANT HONORARY SURGEON FOR WOMEN, MANCHESTER NORTHERN HOSPITAL, ASSISTANT HONORARY OBSTETRIC SURGEON, THE ST MARY'S HOSPITALS, MANCHESTER

I HAVE divided the subject of obstetric haemorrhage into four categories

- 1 Haemorrhage in early pregnancy
- 2 Haemorrhage in late pregnancy and early in labour
- 3 Haemorrhage during the third stage of labour
- 4 Haemorrhage post partum

I do not intend attempting to bring forward anything new in this well worn subject, but to give a general revision, necessarily brief, of the whole subject

I HAEMORRHAGE IN EARLY PREGNANCY

By haemorrhage early in pregnancy I mean up to the twenty-eighth week, the usually accepted period of viability. Such haemorrhage may be due to menstruation during the first two months. After the ovum has settled in *utero* the mucosa of the uterus takes on decidual characteristics, and the decidua consists of three parts—the decidua vera, reflexa, and serotina. The decidua vera and reflexa do not meet and fuse till the third month, so that till that date there is a potential menstruating cavity. This occurrence is rare, and less likely to cause the patient to seek advice than to lead to a miscalculation of the time of onset of labour. Bleeding may be due to the presence of tumours of the cervix, chiefly polyp or carcinoma. It may be due to ectopic pregnancy. In such a case the usual history is that the patient has gone two weeks or so over her time and then started bleeding. Pain on the affected side is a constant symptom, and a decidual cyst of the uterus may be shed. The discharge is characteristically dark and thick. Vaginally an enlarged tube will be felt to the right or left of the uterus.

A tubal pregnancy may die and haemorrhage take place into it and produce a mole, without any serious symptoms save that the uterine haemorrhage continues. The pregnancy may be aborted from the limbril extremity, and remain in the peritoneum, often attached to the end of the tube, and causing the same results as in the last case. The tube may rupture into the layers of the broad ligament, causing haematoma with severe symptoms temporarily, or into the peritoneum, with sudden agonizing pain on the affected side, often fainting, increasing pallor and pulse rate, and falling temperature. This with a history of a missed period presents a picture difficult to mistake for any other abdominal condition. Per vaginam, a pelvic haematocoele, soft and boggy, will be felt in the pouch of Douglas.

The haemorrhage may be due to abortion, and commonly is. We speak of abortion as threatened and inevitable, and the distinction is often difficult to make. I regard abortion as inevitable when there is dilatation of the cervix together with pain and haemorrhage. If haemorrhage be the only sign, I have often known the pregnancy to proceed. For the threatened type absolute rest in bed till all haemorrhage has ceased for at least a week, with small doses of potassium bromide and no violent aperients, constitutes the treatment. In the inevitable, as soon as it is considered that the patient's general condition is suffering from the haemorrhage, and there is no sign of natural abortion taking place, it is best to evacuate the uterus. Up to the third month dilate to the size of the index finger, then remove the ovum with sponge forceps, and make quite sure with the finger in the uterus that evacuation is complete. Afterwards douche with a blunt curette, and pick in a little gauze till morning. I never feel satisfied

about a case unless I have actually had my finger in the uterus. By this means subsequent bleeding and possible sepsis from retained products of conception can often be avoided. After the third month the immediate evacuation of the uterus becomes a very dangerous operation, and the safest plan is to use T aylor's bag, a small elastic rubber bag capable of distension up to six compression of a Higginson's syringe. This bag, with the air expelled and folded up, may be introduced through the undilated or with sinus forceps. It is usually expelled in twenty-four to forty-eight hours and followed by the complete ovum. If not, there is now sufficient dilatation to render evacuation safe and easy. It is more certain and accompanied by less risk of subsequent sepsis than is picking.

In cases where some critical state of the patient may demand immediate evacuation, extreme caution in dilatation is necessary, and if the cervix shows the slightest tendency to split it may become necessary to perform hysterotomy. At all events I consider such an instrument as a Bossi's dilator is always dangerous, and should never be used.

A pregnant becoming molar may lie in the uterus for months without sepsis and often with slight bleeding only. This is the carneous type of mole. In hydatid mole the diagnosis is often difficult. Bleeding from a uterus which is of much larger size than the period of amenorrhoea would indicate, some toxemia, and the passage of hydatid material are the signs. The importance of extra-uterine thorough evacuation must be emphasized, on account of the risks of deciduoma malignum following.

II HAEMORRHAGE IN LATE PREGNANCY AND EARLY IN LABOUR

This group includes two very serious complications—namely, haemorrhage from a normally situated placenta in the upper uterine segment or accidental haemorrhage of two types, concealed and apparent, and haemorrhage from an abnormally situated placenta or placenta praevia in the lower uterine segment, when the haemorrhage is called unavoidable.

ACCIDENTAL HAEMORRHAGE

I first take accidental haemorrhage, which complication of late pregnancy and early labour is characterized by the very great difference in the severity of the symptoms exhibited by different cases. For the most part the symptoms are only slight and cease with suitable measures, but in a smaller number the symptoms are so severe that the case becomes the gravest class the obstetrician is called upon to deal with. Fortunately these severe cases are rare and seldom met with in general practice, but in the practice of a large maternity hospital, drawing abnormal cases from a very wide area, a considerable number are encountered, and it may be of interest and value to analyse a large number of consecutive cases, with the various methods of treatment adopted. There is nothing new or original to be described in the methods of dealing with such cases, and I merely give certain statistics, and the conclusions which may legitimately be drawn from them. For this purpose I have investigated all the cases of accidental haemorrhage admitted to the St Mary's Hospitals, Manchester, during the ten years 1906 to 1915 inclusive—253 cases altogether.

Diagnosis

The most important differential diagnosis is from placenta praevia, for, as I shall presently show, the strict line of treatment in placenta praevia proves one of the worst in cases of accidental haemorrhage. The central and marginal types of placenta praevia present no difficulty in diagnosis but the partial type, where just one edge of the placenta reaches the lower uterine segment, and is almost out of reach of the examining finger, presents a difficulty, and will be apt to be diagnosed as accidental haemorrhage. In such cases the haemorrhage will be slight, as the amount of placenta separated is so small, and it seems to me very likely that most of the slight cases of accidental haemorrhage are really of the above type, especially when the bleeding ceases untreated. It must be remembered that

* A post graduate lecture delivered at the St. Mary's Hospital Manchester March 1st 1924

this may be haemorrhage from the portion of a placenta in the lower uterine segment concurrently with that from a portion separated in the upper uterine segment, which may well account for some cases of placenta praevia not responding to orthodox treatment.

Apart from haemorrhage and inability to feel the placenta, a most important feature in accidental haemorrhage is the presence of albumin in the urine, probably in from 40 to 50 per cent of all cases. In the series under consideration the presence of albumin is recorded only in 51 cases—one-fifth of the whole—but I feel sure that this is due to the fact that the urine analysis was not noted. This brings up the point as to whether there is a predisposition to accidental haemorrhage in cases of toxic albuminuria or not. I incline to the belief that accidental haemorrhage is due to a diseased condition of the uterine wall, for failure to contract and retract after delivery is a notable feature of the condition. On the other hand, the actual bleeding into the uterine wall, and through it into the peritoneum and the broad ligaments, is suggestive of the haemorrhages found in cases of chronic Bright's disease.

In cases of placenta praevia the uterus almost invariably recovers after orthodox treatment, the uterus is healthy, and albuminuria is not a feature. A case of concealed accidental haemorrhage might simulate rupture of the uterus, but the history of absence of severe labour pains, failure to feel foetal parts, and the characteristic hard wooden feeling with extreme tenderness of the uterus, and possibly a greater enlargement thereof than is consistent with the period of amenorrhoea, render a mistake unlikely.

Symptoms

There are, of course, two types of accidental haemorrhage: one when the bleeding is visible, the external or concealed, the other when the bleeding is internal or concealed. It is not unusual to have both types coexistent.

In cases of revealed accidental haemorrhage bleeding in the later months of pregnancy or early in labour is found, and no placenta is to be felt in the lower uterine segment. In severe losses the characteristic signs of haemorrhage will be present. The coexistence of concealed haemorrhage is found out after delivery by the expression of huge dark clots before or with the birth of the placenta.

In concealed cases, with or without any external bleeding, the symptoms are those of internal haemorrhage with rising pulse, falling temperature, and anaemia. The uterus, from the presence of retained blood, may be larger than it should be for the period of amenorrhoea, and is particularly hard and tender.

Prognosis

In severe cases the outlook is bad, as the risk of post-partum haemorrhage is always great. Slight cases do well, often without any treatment at all except rest in bed. The concealed type is extremely fatal, and is one of the most serious obstetric complications met with. Blacker gives the mortality in accidental haemorrhage at the Guy's Hospital Living in Charity as 11.4 per cent in the mother, the foetal mortality is much higher. In my series of 253 cases there were 22 maternal deaths—a mortality of 8.6 per cent. It is a curious fact that 18 of these 22 patients died in the last three years of the series—1913, 1914, and 1915—when there was a great increase in the number of cases admitted suffering from this condition, and the cases were particularly severe and the concealed type was relatively common (Fletcher Shaw²). Of these 22 cases, 14 were of the concealed type, 4 were apparent, and 4 were of the combined apparent and concealed.

I will next consider the results of the present investigation.

Age—The average age of the patients was 33 years.
Parity—Twenty were primiparae, 233 were multiparae—that is a very large proportion of multiparae which is usual.
Maturity—Of the 253 cases, 155 were 8 months and over and 98 cases under 8 months. Of the 155 cases, 78 were at term of the 9th, 74 were at 7 and 7½ months.
Type—There were 203 cases of apparent haemorrhage, and 50 cases of concealed and concealed and apparent together.
Albuminuria was recorded in 51 cases only.
Mortality—Among the 253 cases there were 22 maternal deaths (8.6 per cent) and 196 foetal (176 stillborn, 20 died) a percentage of 77.

Treatment

In 19 of 109 slight cases the bleeding was arrested without obstetric treatment, and the patients were sent home undelivered and well to proceed to term if possible. The remaining 90 slight cases also received no obstetrical intervention and were treated by rest in bed the bleeding ceasing and delivery taking place naturally. They all recovered. Of the children, 45 were living and 45 stillborn. The remaining cases were treated by the methods shown in the table, which also gives the results to mother and child.

Results of Different Methods of Treatment

Treatment	No. of Cases	Mothers		Children		
		Living	Died	Living	Undelivered	Still born
Nil	109	109	0	45	19	45
Ruptured membranes	66	62	4	15	0	51
Plugging	23	22	1	3	0	23
Forceps	8	5	3	0	0	8
Version	20	13	7	4	0	16
Caesarean section and hysterectomy	16	10	6	1	0	15
De Ribes's bag	9	8	1	3	0	6
Vaginal hysterotomy	2	2	0	0	0	2

From the table we find that the method of treatment most commonly adopted was that of rupturing the membranes, applying a tight binder, and administering ergot or pituitrin. The number so treated was 66, and of these 4 died. With regard to these latter, the notes state that one was a bad cardiac case, one died almost immediately on admission, and the other two died of post-partum haemorrhage.

The method next in frequency was plugging the vagina with rupture of the membranes in 23 cases, one of which died. This patient had the packing in for some days before admission, and gangrene had set in. *Post mortem* the *B. aerogenes capsulatus* was found to have invaded most of the abdominal organs. Version was performed in 20 cases, with 7 deaths. Four of these cases are stated to have been moribund on admission. One was a case of eclampsia and died from this cause. The other two died of post-partum haemorrhage.

Caesarean section with hysterectomy was performed in 16 cases of severe concealed haemorrhage, and of these 6 died. All were in *extremis* on admission, and it may be considered lucky that 10 recovered.

Champetier de Ribes's bag was used in 9 cases, with one death.

Forceps application after manual dilatation of the cervix was resorted to in 8 cases, with 3 deaths.

Vaginal hysterotomy with delivery by forceps or version was performed in 2 cases successfully.

Summary of Results

Rupture of the membranes etc., a mortality of 8 per cent	
Plugging the vagina	4.3
Version	35.0
Caesarean with hysterectomy	37.5
Champetier de Ribes's bag	11.0
Forceps	37.5
Vaginal hysterotomy	0.0

It is to be remembered that in all those cases where obstetric treatment was adopted the condition of the patients was critical. Of those who died 20 were multiparae, 2 primiparae, 5 were at term, 17 were premature, 14 were severe concealed haemorrhage cases, 4 were apparent, and 4 were of the combined type.

Conclusions

It seems fair to draw the following conclusions:

1. Plugging, I know, is often regarded as the best treatment, especially for general practice. The drawbacks to it are that it may predispose to sepsis, but this largely depends on the material to hand and the assistance

available. At the Rotunda Hospital, Dublin (Hastings Twcedy³), it is the routine treatment for every case of accidental haemorrhage. As carried out in that hospital it is claimed that the pulsation in the uterine arteries is stopped by the method. The collateral circulation is, however, so free that plugging the vagina appears to me to be insufficient to effect this. The method has perhaps hardly been given a fair trial in Manchester. In the carefully packed cases that I have observed the plug has gradually become saturated and slippery with blood, and has eventually slid out of the vagina, the bleeding still continuing. In cases of partially concealed bleeding I cannot conceive that it is sufficient, and it is apt to give a sense of false security. I feel inclined to regard it as a good temporary measure to be adopted in cases of moderate severity, and only after the next method has been given a good trial.

2 Rupture of the membranes, application of a tight binder, and the administration of ergot or pituitrin has been and still is the method chiefly adopted in Manchester at St Mary's Hospitals. Four out of the 66 cases so treated died, they were in an almost hopeless condition on admission. This treatment is all that is necessary in most cases, it is simple to carry out, and is very largely free from the risk of subsequent sepsis. It is the method that appeals to me most of all for the average case where the patient is constantly under the practitioner's eye. Should he find that uterine contractions are not provoked, and that although external bleeding has ceased the patient does not improve, it is reasonably certain that the case is one of concealed bleeding also, and in many cases like this operation holds out the only hope, and then only if not too long delayed.

3 This brings us to Caesarean section, usually combined with supravaginal hysterectomy. I have had the opportunity of seeing most of the cases so dealt with in this series, and in all of them the uterus was sodden with blood, the broad ligaments were filled with blood, and there was free blood in the peritoneum. The uterus in all cases made no effort to contract after the Caesarean section, and so was removed. Fortunately these severe cases are very rare. In the present 253 cases there were only 14 concealed and 4 concealed and revealed combined, 16 were treated by Caesarean section and hysterectomy, and 6 died. Remembering the cases, I feel that it was a great matter for congratulation that 10 were saved. I am convinced that this method is the only one that holds out any hope for a case with rapidly rising pulse and falling temperature, a particularly hard uterus, possibly distended to a size greater than would be expected for the corresponding period of amenorrhoea, and very slight or no external bleeding to account for the patient's condition. Such cases are best in hospital, and even then the outlook is bad.

4 Version, such admirable treatment in cases of placenta praevia, is to be condemned in accidental haemorrhage. One-third of the cases so treated died, and those who did not were probably cases of partial placenta praevia.

5 Forceps application, like version, has really no place as a method of treatment for accidental haemorrhage.

6 De Ribes's bag was used in only 8 cases. It often fails to excite any contractions, and so necessitates some further treatment after it has been removed. Further, it is difficult to insert, and it is seldom at hand when required.

In brief, the average case of accidental haemorrhage is met by rupture of the membranes, a tight binder, and ergot. In slighter cases merely rest in bed suffices. Plugging the vagina may be combined with the above, but greatly increases the risk of sepsis, and may, if the doctor is obliged to leave the case for a time, disguise to the nurse the symptoms of concealed bleeding.

No rapid method of evacuation of the uterus is in these cases to be considered for a moment, unless it is feasible to go on to the performance of hysterectomy. For this reason both forceps and version are contraindicated in the treatment.

The absolutely and many of the partially concealed types of accidental haemorrhage are only to be treated by hyster-

ectomy, and are best in hospital, unless the home conditions are ideal.

PLACENTA PRAEVIA

I will now consider in a much more cursory manner some aspects of cases of placenta praevia which occurred in the same period of 1906 to 1915.

The number of cases admitted was 405, and of these 36 died, a mortality of 8 per cent.

Of the children, 251 were stillborn—that is, 61 per cent, further, of these 405 cases, only 102 were at term, and 301 were premature. Thus three-quarters of the children were premature on delivery.

There were only 42 primiparae in the series of 405 cases, showing the comparative rarity of the condition in first pregnancies.

Thirty-six patients died. Of these, 14 are recorded as having been moribund on admission, and only surviving for a very short time. It is, of course, to be expected that many such desperate cases are admitted, often after a long journey by ambulance. They are literally bled white and cannot be expected to rally. Ten cases died after version combined with extraction of the foetus. This line of treatment, which has as its aim the production of a living child, was tried for a brief period and has now been quite abandoned. The child being so often premature, there is little to be said for a method of treatment which places the mother's life in jeopardy also. Four cases died after dilatation and forceps extraction, which is only to be compared with version and extraction and has little to recommend it. One case died after version without extraction of the child, and may in all probability have been a case of accidental haemorrhage.

The remaining seven cases died from extraneous causes as follows. Two from eclampsia, one from each of the following complications—eclampsia, pneumonia, puerperal sepsis, a fibroid complicating labour, uterus ruptured after version, and one died under chloroform.

The Methods of Treatment

Eighty-one cases delivered themselves naturally. Version was performed in 220 cases, leaving the uterus to expel the foetus itself. Eighteen cases are recorded as living, version performed with extraction of the child. This figure is probably too low, and should include some of the cases simply recorded as version. De Ribes's bag was used in 26 cases. It has the disadvantages referred to under accidental haemorrhage. In 12 cases the vagina was plugged—a risky method from the point of view of subsequent sepsis, and not an efficient one. Seventeen cases were delivered with forceps, which method has all the disadvantages of version with extraction. Six were cases of breech presentation and a foot was pulled down. In 11 cases the membranes were ruptured. In 2 cases Caesarean section was performed.

Conclusions

The broad results of these figures, I consider, bring out the following points, which are now, of course, well established.

1 That when we have a living foetus at term, and in a case of central placenta praevia, especially in a primipara, Caesarean section is the operation of election. Version in a primipara at term, with the difficulty in dilatation of the soft parts of the parturient canal, is bound to be a troublesome proceeding, and the child is sure to be sacrificed. Caesarean section is undertaken with so little risk that a lippy result for both the mother and child can be practically promised.

2 In all premature cases the foetus is not to be considered. A foot must be pulled down and a weight attached to it. This invariably arrests the haemorrhage and gives the patient time to recoup her loss of blood and to have salines and restoratives administered to her. The uterus in the meantime will recover, expel the child and the placenta, and this without further loss of blood. If the child is born alive, it is all to the good.

3 There are a few slight cases of marginal and partial placenta praevia where rupture of the membranes suffices

to stem the bleeding, and delivery may take place naturally. Should the bleeding continue, version must be undertaken, and it is a much more difficult operation after the waters have been drained away.

One may almost say that the treatment of placenta previa resolves itself into version and allowing the uterus to expel the foetus, with two exceptions. First, in a primipara at term with a central placenta praevia, Caesarean section must be insisted on for the sake of both mother and child. Secondly, in a multipara in the same case Caesarean section may be suggested if a living child is especially desired. If not, version is the treatment. However great the temptation to terminate the case either by version with extraction or by forceps extraction, this temptation must be resisted.

Post-partum haemorrhage is a subject closely associated with the two foregoing conditions.

Severe uncontrollable post-partum haemorrhage is only met with in cases where a uterus which is not contracting has been suddenly emptied. In placenta praevia this extra loss is sufficient to kill the patient before the uterus has time to recover. In accidental haemorrhage the same occurs, only the uterus would probably not recover its tone anyhow. I have already indicated how with due care these misfortunes may be avoided.

The average case of post-partum haemorrhage following unduly prolonged labour or overdistension of the uterus by twins or by hydramnios as a rule readily responds to massage of the fundus and pituitrin, or careful control by a hand on the fundus for a judicious period of time. Taking this, bimanual compression of the uterus, taking the opportunity to ascertain that the uterine cavity is quite empty of secundines, possibly combined with a hot douche, generally meets the case. Compression of the abdominal wall often gives the uterus time to contract successfully and retract, and so stop the bleeding. The question of the treatment of post-partum haemorrhage is so well worn that I will not dwell on it. A great percentage of the cases respond to any of the accepted forms of treatment. Those that do not generally die unless it is feasible to perform hysterectomy, and thus, hoping against hope, is generally postponed until it is too late.

III HAEMORRHAGE DURING THE THIRD STAGE OF LABOUR

Some of the most alarming cases with which we have to deal in midwifery are those of severe bleeding while the placenta is still *in utero*. This is due to a partial separation of the placenta, and this separation itself is generally due to efforts to expel the placenta by pressure on the fundus before it is naturally separated from the uterine wall and has passed into the vagina. The signs of this having happened—rising up of the fundus, uterus smaller and flatter from front to back, escape of molar cord, and slight gush of blood—are well known. In a partial separation thus brought about, the bleeding is often extremely severe. Attempts at expression will have failed, and the only treatment is to pass the sterilized hand into the uterus, complete the separation with the fingers, give 5 ccm of pituitrin, and maintain a firm grasp of the fundus till the uterus is and remains firmly contracted. This is what the midwives are now taught to do in extreme cases where they find it quite impossible to get a medical man in time to save the patient's life.

IV SECONDARY POST-PARTUM HAEMORRHAGE

Haemorrhage occurring after the first twenty-four hours may be due, first, to retained products of conception, often a small piece of placenta or placenta succenturiata, or, more rarely, membrane, secondly, to getting up too soon, or overexertion, and not infrequently as a sequela of puerperal sepsis.

The treatment is to clear out the uterus, and swab it out afterwards with tincture of iodine, and pack with gauze for twenty-four hours.

CYESOEDEMA: A PECULIAR BLOATING OF PREGNANCY

BY

A A LENDON, M D Lond,

HONORARY LECTURER IN OBSTETRICS, UNIVERSITY OF ADELAIDE

THE object of this somewhat bizarre heading* is to attract attention to an accompaniment of pregnancy which I have seen very pronounced in 6 out of 363 consecutive cases of midwifery since I first observed the condition in 1901.

It is a peculiar bloating or swelling, which is quite distinct, on the one hand, from anasarca or ordinary pitting dropsy, and, on the other hand, from the solid swellings, such as myxoedema, which it certainly more nearly resembles.

It affects the whole body, but naturally it attracts more attention in the face, as it so greatly alters the features of a young woman as almost to make her unrecognizable towards the end of pregnancy. In my experience it has occurred only in primiparae, it disappears with considerable rapidity after the labour is over, it has not occurred in my cases in subsequent labours, though not specially associated with post-maturity according to the maternal reckoning, the babies have been large—in three instances they weighed on the average just under 8 lb, and in two other cases were described as very large. In two cases there was some albuminuria, but no other recognized indication of the so-called toxæmia of pregnancy.

To describe eyesoedema is a matter of some difficulty, and I must confess rather beyond my powers. I was never able to induce a victim of it to sit for her photograph. There is no accompaniment such as the slow speech of myxoedema, nor the supraclavicular fatty masses, there is no senso of general ill health complained of. There is not the pallor of renal oedema, nor the porcelain clun tint to be seen in the cheek. There is rather some lividity, but happily it does not suggest alcoholic indulgence, it has not been associated with high blood pressure, though the cases mostly were observed before the sphygmomanometer came into general use.

Of one of these cases I have lost sight, of the remainder four agree in this respect—that they have all become stout in middle age, and three have undergone treatment for obesity.

What is its nature? It is certainly not due to nephritis, and I think that hypothyroidism may be ruled out of the question. I have failed to find any description of eyesoedema in any textbook in our university library, but Whitridge Williams refers to "the non-oedematous" (presumably non-pitting) "thickening of the features observed in so many pregnant women," and suggests that it may be related to hypertrophy of the anterior lobe of the pituitary body, which, he says, has been "shown to undergo regularly great hypertrophy during pregnancy and to atrophy after the termination of the pregnancy."

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

THE NON-LUTIC ARGYLL ROBERTSON PUPIL

In my experience the phenomenon of this form of Argyll Robertson pupil reported by Mr Foster Moore (November 7th, p 843) is not uncommon, and to the features described by him I would add certain others which appear to me no less important—namely, that the condition occurs more often in women than in men, and that when unioocular it is (or has been in all my cases) the left eye which is affected. In a paper entitled "Emotion and eye symptoms," read in 1921 before the Medical Section of the British Psychological Society, I referred to several of these cases, whose history strongly suggested that the unequal pupils were the result of emotional stress, and in each of these it was associated with the death of the father. This led me to regard the phenomenon as a disorder of the sympathetic nervous system, and

* Kypsis pregnancy οίδημα, swelling

in pursuance of this theory I have for some time been engaged in an investigation, the results of which I hope shortly to publish. Mr Foster Moore's interesting communication prompts me to anticipate matters and to record one striking example which bears out his observations and furnishes him with another instance of familial tendency.

A lady, aged 32, consulted me in 1915 and again in 1916 on account of some difficulty in reading. Beyond a low degree of compound hypermetropic astigmatism nothing abnormal was found. In May 1921, she attended again, complaining chiefly of headache. The left pupil was found to be larger than the right, and to react to accommodation but not to light. The Wassermann reaction was negative. As she was of the type commonly described as 'highly strung' I surmised that some shock or grief might have caused the symptom and asked her if she had had any recent bereavement. To my astonishment she burst into tears and then told me of the death of her father, which had occurred, not immediately before, as one might have supposed, but fourteen months previously, in March 1920. On the anniversary of his death she was on her way to visit his grave, and was actually buying a wreath, when her sister noticed and commented upon the dilatation of the left pupil which was so pronounced as to give her a strange look. I saw her again in March, 1922. She was then unaware that it was about the time of the second anniversary of her father's death. The pupils were at first normal in size and reaction, but a reference on my part to the old sorrow, whilst evoking no apparent emotion, was yet followed by a dilatation of the left pupil. The patient said that she had noticed that the equality of pupils was disturbed by certain actions and instances going upstairs. She came again in the following March, complaining of a sensation of squinting when she looked to the left. She had no diplopia, and the only muscular imbalance was 2 degrees of exophoria. The left pupil was found to be larger than the right, but a few minutes later they had become equal.

It was only later that, by chance, I found in the notes made on her elder sister who had consulted me in 1920, the entry 'Left pupil larger than right. Patient states that for many years the left pupil has been much greater than the right, at times feeble reaction to light. Nervous breakdown after death of father in previous March. Similar attack more than twenty years ago, when he was about to be married and then could not determine to leave parents, although banns were twice declared.' Some eleven years later she eventually married the man to whom she had been previously engaged.

These are only two of a number of cases which have led me to the conclusion that the conditions described by Mr Foster Moore are to be attributed to an emotional rather than to an infective or toxic factor.

Portsmouth

W S INMAN

The following case is of interest, in view of the eight cases mentioned by Mr R Foster Moore in the *BRITISH MEDICAL JOURNAL* of November 7th (p 843).

In the course of a routine examination a woman, aged 33, who made no complaints as to her eyesight, had been twice married, and had had a healthy child by each marriage, was found to have an Argyll Robertson pupil, there was no history and no signs of syphilis, the knee-jerks were present, and there were no other nerve symptoms. The Wassermann test of the blood serum was negative, as also of the cerebro-spinal fluid in all dilutions. Cells 5 per c mm, globulin slight excess, Lange's gold test 0000000000.

I am indebted to Dr H M Galt for the examination of the blood serum and the cerebro-spinal fluid, and to Lieut-Colonel H Herbert for kindly examining the patient's eyes and supplying me with the following report.

The Argyll Robertson pupil is definite in the right eye only, and is associated with some miosis. The latter, however, is evidently inconstant.

The patient was seen on two days at a week's interval. At the first examination the right pupil was definitely contracted, the left being perhaps very slightly dilated and irregular in shape from flattening of part of its curve. An unexplained slight transient enlargement of both pupils was noticed. On the second day both pupils were larger than before. The right was of about normal size (2 mm) except during accommodation and the left was somewhat dilated throughout measuring quite 3 mm in its greater diameter. No reaction to light was obtainable in either eye. With the left eyelids closed a very moderate contraction of the right pupil took place with maximal accommodation. If then the left palpebral aperture was opened that eye was found to be slightly divergent or at least not at all convergent. Accommodation being maintained full convergence followed, together with increased contraction of the right pupil. Comparing the two stages of pupillary contraction, the second movement with convergence, always appeared greater than the primary movement, associated with accommodation. The only corresponding contraction of the left pupil was a barely discernible one, with combined maximal accommodation and convergence.

The vision was 6/5 in each eye and accommodation was unimpaired; the fundi were normal. The pupils dilated readily with homatropine, the effect was equal in both eyes, the left pupil remained slightly the larger of the two.

RESPIRATION AND ANAESTHESIA

At a meeting of the Anaesthetics Section of the Royal Society of Medicine held on December 4th, with the President, Dr F E SHAW, in the chair, a paper on the subject of apnoea, dyspnoea, and cyanosis in relation to anaesthesia was communicated by Professor M S Pembrey, F R S, and the President.

Physiological Considerations

Professor PEMBREY stated that anaesthesia was a pathological condition which had its representation in physiology, for it was impossible to discover any change which was unique. The same life and death were observed by the pathologist and the physiologist, the difference lying in the conditions of the subject and the mental attitudes of the observers. Mutual benefit would therefore result when anaesthetists and physiologists compared their findings. The present discussion would be confined to respiration. By apnoea was meant the absence of respiratory movements whereby the lungs were ventilated. In the foetus there was a profound and long apnoea before birth, though the mechanism for pulmonary ventilation was present in reserve. A foetus born before full term was capable of breathing, and this might be considered an exception to the rule that muscular work needed progressive training, trial and error, but Ahlfeld had shown that muscular contractions of a rhythmic nature occurred within the uterus, and appeared to be respiratory and due to stimulation of the medulla by gaseous changes in the blood. Colnstein and Zuntz removed a foetal sheep from the uterus without damage to the placental circulation, and found that stimulation of the skin did not cause respiratory movement, but the animal began to breathe as soon as the umbilical cord was tied. Undue importance had been given to cutaneous stimulation as the cause of the first breath, but it was well known that if the placental circulation were intact the foetus could be subjected to much manipulative treatment, in cases of complicated labour, without being stimulated to breathe prematurely in the uterus. The effective stimuli resulted from changes in blood composition, and cutaneous stimuli were only an accessory influence upon the respiratory centre, the excitability of which was low in the foetus and infant, as they could withstand deprivation of oxygen and accumulation of carbon dioxide better than the adult. The young mammal retained characteristics of its cold-blooded ancestors. A cat could not survive submersion for three minutes, but a two-day-old kitten would recover after being under water for as long as twenty minutes.

Apnoea signified diminished excitability of the nervous system and the absence of sufficient carbonic or other acid to stimulate the respiratory centre. Apnoea was not due to excess of oxygen, as could be demonstrated by observations on hibernating animals, the respiratory movements of which differed in type according to the activity and temperature of the animal. When the temperature was below 12°C the periods of apnoea lasted several minutes with few respirations between, when the temperature rose above 15°C the apnoeic periods were shorter and the periodicity of the breathing resembled that of the Biot or that of the Cheyne-Stokes type. The excitability of the animal was much depressed, there was muscular rigidity, which resembled that of a man during unconsciousness produced by lack of oxygen. In infants, Cheyne-Stokes breathing commonly occurred and was physiological. The same type of breathing was seen in the old and might have no relation to disease, being due to diminished excitability of the central nervous system. Morphine would produce periodic breathing, often of the Cheyne-Stokes type, hence the success of the old ambulatory treatment of morphine poisoning could be explained by the production of carbonic acid in sufficient quantity to stimulate the depressed respiratory centre. Yandell Henderson had shown the value of 5 per cent carbon dioxide in such cases. The injection of morphine might lead to serious respiratory failure, and the injection of adrenaline into anaesthetized

animals might produce Cheyne Stokes respiration. The classical type could be abolished most readily by giving air mixed with 3 or 4 per cent carbon dioxide. Analyses of the alveolar air showed a low tension of oxygen and a high tension of carbon dioxide at the beginning of the period of breathing and the opposite during the last waking breaths. This periodic breathing was due to diminished excitability of the central nervous system, together with defective supply of arterial blood, the CO₂ accumulated and the O₂ diminished until the nerve cells were stimulated, inspiration began and culminated in hyperpnoea or dyspnoea, CO₂ was washed out, and sufficient O₂ taken into the blood, apnoea followed owing to insufficient CO₂ to stimulate the centre. Air containing more than 2 per cent of CO₂ abolished apnoea by maintaining the tension of that gas at its stimulating value. Pure oxygen given by a mask and valves abolished apnoea by maintaining the partial pressure of CO₂ in the blood at its stimulating value. The forebrain impulses resulting in excessive ventilation and the washing out of the CO₂ from the alveoli were thereby avoided. Air containing less than the usual quantity of oxygen abolished apnoea owing to steady stimulation of the centre. Historical cases sometimes exhibited Cheyne Stokes respiration, but this could be cured by suggestion. Piton and Huxley had described another type of apnoea—the postural apnoea of diving birds. A duck with the neck held out, as for diving, would cease to breathe and a long period of apnoea resulted. The impulses arose in the neck muscles and in the labyrinth, for apnoea could not be produced if the corresponding nerves had been divided. Reflex inhibition of inspiration was the chief factor leading to anoxaemia and death in cases of drowning in a few inches of water, whether the act were voluntary or accidental. Forced breathing caused apnoea, enabling a man to remain a long time under water after a dive. This was dangerous, however, as it might lead to anoxaemia, unconsciousness, and death, it might, by washing out the CO₂, produce apnoea. As long ago as 1876 Adamell Hewson of Philadelphia published a paper on the analgesic effects of rapid breathing and operated on patients after such breathing. Fifty breaths a minute for three to five minutes were necessary for the production of the requisite analgesia. The condition was one of cyanosis, as shown by the colour of the patient and the blood. Rigidity varied considerably. In conclusion, Professor Pembrey said that as it was of fundamental importance in relation to anaesthesia, the question of apnoea in health and disease had been gone into fully. The respiratory movements indicated not only lung ventilation but also the excitability of the central nervous system and were more informative to the anaesthetist than an examination of the pulse. Dyspnoea was the counterpart of apnoea. The former was evidence of vigorous respiratory stimulation, the latter denoted its absence.

The Anaesthetist's Point of View

The President (Dr Shipway) dealt with the subject from the point of view of the anaesthetist. The instruction, "Breathe deeply," might cause apnoea, as too much CO₂ was washed out. Respiration should be natural and easy. Rapid induction could not be obtained without a sense of discomfort, since the supply of oxygen must be cut down to get the necessary anaesthetic tension in the blood. Apnoea might occur during an anaesthetic. It was rare when chloroform was given through a tracheotomy tube, as the intake of air was unimpeded and the supply of oxygen was adequate in relation to the rise of CO₂. Apnoea as a complication was most likely to arise during intra-tracheal insufflation if the ventilation was excessive and the CO₂ washed out. In a case recorded by the authors an average ventilation of 16 litres of air a minute was sufficient to oxygenate the blood, but 30 litres a minute produced apnoea for a period of two minutes, the pulse was very good and the blood pressure was 155 mm. at the commencement of the rapid ventilation. After a minute it had fallen to 138 mm. During the period of apnoea it gradually rose again to 150 mm. The patient then commenced slow voluntary breathing. A sample of alveolar air taken when the respiration recommenced showed CO₂ percentage to be

6.04, or about normal. Samples of air taken during the operation showed that the blood pressure followed the CO₂ tension. Apnoea might occur during prolonged gas-oxygen anaesthesia, when expired air was allowed to escape through valves, and this could be abolished by instituting re-breathing. The presence of CO₂ in excess caused sweating, flushing, and rapid breathing, with a fall in pulse rate, but if there was a lack of CO₂ the opposite phenomena were seen—pallor, cold clammy skin, shallow breathing, and a quickened pulse. This condition was now seen less frequently, as modern apparatus made provision for re-breathing. The apnoeic phenomenon was often mistaken for shock, but apnoea leading to apnoea was seldom seen, as the lack of oxygen and formation of lactic acid in the tissues stimulated respiration. The danger of reduced partial pressure of CO₂ in the blood was increased during gas oxygen anaesthesia if at the same time there was a deficiency of oxygen in the air inspired. Lactic acid formed during anoxaemia acted similarly to CO₂ on the respiratory centre and on the dissociation of oxyhaemoglobin. Apnoea seldom occurred during "open" ether, as the method was really a semi-open one. Analyses of air under such masks had shown that the percentage of CO₂ was adequate to stimulate breathing. The percentage ranged from 2 to 4. With chloroform anaesthesia apnoea might lead to syncope, if followed by a resumption of breathing of a concentrated vapour. The action was direct on the heart. It might also occur during anaesthesia in old persons and those suffering from arterio-sclerosis. Cheyne-Stokes breathing could be abolished by oxygen or CO₂. It was caused by lowering of the arterial pressure induced by the depressant action of the drug. The respiratory centre was also depressed and the rate of blood flow reduced. The tissues were starved of oxygen, but anaesthesia reduced the metabolism, and the tissues did not call for so much oxygen. It was therefore unnecessary to give oxygen as a routine, for if Cheyne-Stokes breathing arose it could best be abolished by substituting a semi-open for an open method, and both on physiological and anaesthetic grounds the semi-open method made its appeal. Excess of CO₂ produced hyperpnoea and dyspnoea, and was caused either by excessive re-breathing or by obstruction of the airway, in the latter case associated with lack of oxygen. If morphine or scopolamine were given (even with the addition of atropine) re-breathing should be instituted almost from the start and increased later to promote anaesthetic absorption. Even if the percentage of oxygen given were high it might be insufficient to oxygenate the blood in the absence of re-breathing. The effect of excess of CO₂ and lack of O₂ caused by obstruction might be so great that it had been well said that anaesthetic difficulties and dangers lay largely above the larynx. Excitement and struggling during induction were largely asphyxial in origin, irregular strengths of vapour giving rise to reflex phenomena, such as swallowing, breath-holding, and feelings of suffocation when the concentration was high. Even the most difficult subject could be made to pass into anaesthesia, by ether given by the drop method, without a struggle if the strength of vapour were increased gradually. Again, the use of oxygen during induction, when cyanosis was present, eliminated or cut short the period of struggling. The most interesting of the signs of lack of oxygen—interesting because so often overlooked as to its significance—was the onset of rigidity and clonic muscular movements, which might be regarded merely as evidence of light anaesthesia. Abdominal rigidity had long been known as possibly due to anoxaemia, and it could be abolished by oxygen. During the third stage of anaesthesia, when all the other signs pointed to deep anaesthesia being present, clonic movements might occur, such as piano playing movements of the fingers and hands, accompanied by jerky adductor movements of the arms, and irregular movements of the shoulders. These athetotic movements were of great importance, as they were due to lack of oxygen, and were therefore more common under chloroform or its mixtures than under ether. Whatever the anaesthetic, early recognition of their nature was obviously essential to ensure free ventilation of the lungs. They were frequent in the anaemic, feeble subject, especially if induction had been rapid. The question then arose whether it was necessary to give oxygen

in uncomplicated cases. On physiological grounds it would appear to be unnecessary, for the utilization of oxygen by the tissues was so much reduced that the essence of anaesthesia might be said to be a reduction of oxidation. Indeed, it was possible to give an excessive amount of anaesthetic where the colour of the patient was good owing to the abundance of the oxygen supply. The aim of respiration was the adjustment of oxygen and CO_2 . The real seat of respiration was in the tissues. The tissues, not the oxygen, determined the process of oxidation, which was characteristic of life. The colour of the blood was an indication of its oxygen content, but might be no guide to the activity of the tissues. Further, the use of oxygen in uncomplicated cases might tend to disguise a faulty administration. Mucus in the trachea, churned up and aerated, represented a real danger, particularly in a patient with a feeble or dilated heart. If present in the smaller tubes the difficulties were almost insurmountable, as appeared very clearly from a case details of which had been given to Dr Shipway.

On the conclusion of the paper, owing to the lateness of the hour it was not possible to allow of much discussion, and the few speakers confined their remarks to questions on points mentioned by the opener, who briefly replied.

GENITO-URINARY TUBERCULOSIS IN THE MALE

At the meeting of the Medical Society of London on December 14th a discussion was held on the treatment of genito-urinary tuberculosis in the male. Sir HOLBURN WARING was in the chair.

Mr CYRIL A. R. NIREN, who opened the discussion, said that it was most convenient to start with the kidney, for a lesion in the kidney was very commonly the primary focus from which the lower urinary tract was directly infected. The bacilli reached the kidney from some other focus in the body, either a quiescent and obscure lesion like a tuberculous mediastinal gland, or an active and obvious source like pulmonary, articular, or osseous tuberculosis. These two sources of infection, generally speaking, gave rise to two distinct clinical types of renal tuberculosis. One of these was surgical, primarily unilateral, and characterized by caseation and ulceration, while the urine contained tubercle bacilli, caseous material, pus cells, and a small trace of albumin of pyogenic origin. The other, the medical form, was bilateral, the renal parenchyma was studded with urinary tubercles, and the urine was clear, containing a few bacilli, many casts, and a large trace of albumin of sanguineous origin. As surgical renal tuberculosis was primarily unilateral and as spontaneous cure was practically unknown, the treatment was early nephrectomy, but before the operation was performed the function and condition of the opposite kidney must be carefully investigated. After nephrectomy the condition of the bladder often improved rapidly, but in 40 per cent of cases local and general treatment was required for a considerable time. The contraindications against nephrectomy were (1) when the function of the opposite kidney was defective (unless the deficiency was solely due to the accompanying toxic nephritis), (2) in advanced bilateral tuberculosis, (3) when the disease was secondary to pulmonary or other gross tuberculous lesions. Most surgeons (Mr Nitch continued) divided the ureter in the lumbar wound as far as possible from the kidney, either with a cautery or between two ligatures after injecting pure phenol. His own practice was to remove the entire ureter whenever it was obviously diseased, with a view to preventing further infection of the bladder and also accelerating its recovery. The results justified the operation, and in twenty-two cases there had not been any operative mortality. Ureterectomy might not be considered necessary in every case, but it was definitely indicated as a primary operation when the ureter was much enlarged and dilated, for in such a condition high division was often followed by a urinary fistula in the loin. Secondary ureterectomy was indicated when persistent cystitis was obviously caused by discharge of tuberculous material from the ureter, also for a lumbar urinary fistula, and for a persistent tuberculous sinus. With regard to vesical tuberculosis, which was almost

always secondary to renal or genital tuberculosis, the immediate treatment consisted in removing either the affected kidney or the affected portion of the genital tract. When the disease was complicated by both renal and genital tuberculosis, the kidney must be removed first and the lesion of the genital tract at a later date. The results of such drastic treatment were often so remarkably good that extension of the disease to the genital tract after nephrectomy should not deter the surgeon from a second radical operation. In many cases the bladder eventually recovered without further treatment, but in about 40 per cent a persistence of pollakiuria and pyuria called for both general and local treatment. General treatment consisted of rest, bladder sedatives, cod liver oil when tolerated, and tuberculin. The best form of local treatment was surgical diathermy at intervals of a fortnight or three weeks, the electrode being introduced through a catheterizing cystoscope and the granulation tissue or ulcer carefully fulgurated. Mr Nitch left the subject of genital tuberculosis to the speaker who followed, but he mentioned that in the treatment of tuberculous epididymitis he had found the operation of epididymo-vesiculectomy devised by Loughnan gave excellent results, the removal of a portion or the whole of the prostate was necessary only in advanced cases. A post-operative course of tuberculin improved the general condition.

Mr KENNETH WALKER said that it was impossible to discuss the treatment of genital tuberculosis without referring to its pathology. The first lesson that pathology taught was that genito-urinary tuberculosis was always the result of a focus elsewhere in the body, most commonly in the lungs, the bones, or the lymphatic glands. The post-mortem room demonstrated the frequent association of tuberculosis of the genitalia with similar lesions of the urinary system, but a false impression as to frequency might be obtained thereby, owing to the fact that what was seen in the post-mortem room was only the advanced stages of the disease. Combining figures from various sources, including the consulting room and the out-patient department, he was inclined to think that only in about 45 per cent of cases was the urinary system attacked in conjunction with the genital. As a rule the disease appeared first in the urinary system, and from there spread to the genitalia. There seemed to be no records of the frequency with which the disease took the reverse course, from the genitalia to the urinary system. His own feeling was that when a genital tuberculosis spread to the urinary system it was the bladder that became infected through the prostate and seminal vesicles, and that the appearance of a renal lesion almost always meant that the infection started primarily in the kidney. The direction taken by the disease in the genitalia was a matter of controversy. He believed that the path taken by the tubercle bacillus was the same as that taken by the gonococcus or by any other organism that was known to attack the urethra primarily, and the epididymis by secondary spread down the cord. He regarded the prostate and vesicles as playing a very sinister part in the spread of tuberculosis from the urinary to the genital systems. The prostate furnished a bridge between the two systems along which infection passed. To those who objected that, if the spread was from the prostate to the epididymis, lesions of the prostate and vesicles without involvement of the testicles should be more common, he answered that such cases frequently occurred, but were often missed. Provided the intral mucous membrane was not involved, tuberculosis of the prostate and of the vesicles produced few signs or symptoms. A rational treatment, based on this pathology, must forbid entire reliance upon surgery. General constitutional treatment was as important as local extirpation by the knife. In many cases surgery was adjunct to treatment by open air, diet, cod liver oil, tuberculin, "artificial sunlight," and so forth. If the case was one of pure genital tuberculosis—on the whole a benign disease—the tendency was towards encapsulation and cure. The first step, therefore, in the treatment of a patient was to make sure that there was no disease of the urinary system. Should a focus be found in the urinary tract surgical measures must be adopted. Once the urinary condition had been satisfactorily dealt with an improvement would take place in the genital disease, and constitutional measures would begin to

take effect. Again, if the theory was accepted that the disease most commonly started in the prostate and vesicles and spread to the epididymis, obviously even such a wholesale measure as castration must fail to eradicate it. Should the aim of the surgeon be to remove entirely by means of the knife the infected tissue, he could only do so by means of a complete extirpation of the genital tract. Whatever might be thought of Mr. Hampton Young's radical operation, it must be admitted that it was the only logical one from the point of view of complete removal of infected tissues. To remove the testicle and to leave behind an infected prostate and vesicle was an incomplete operation. It might be justifiable, but it must be recognized that all that had been done had been to remove grossly infected tissues in order to assist the body to overcome the infection that remained. The operation of total extirpation of the genital tract should be reserved for cases which had failed to respond to other measures. In the majority of cases the only surgical measures required were epididymectomy, orchidectomy, the opening of abscesses, and the scraping of sinuses. In all cases in which the body of the testis was healthy, or in which such foci as existed could be removed without damage to the blood supply, the testis should be left behind. Bilateral castration was never justifiable. Of the procedures he preferred epididymectomy, and it was surprising how little the patient appeared affected by this operation.

Dr. STEPHEN GLOVNE contributed some observations from the point of view of a pathologist. He thought that in cases of doubt as to the presence of the tubercle bacillus it was best to collect all the urine for twenty-four hours. In a twenty-four hours' specimen he had found numbers of tubercle bacilli which he felt sure he would not have found in the small quantities usually sent. Judging from some recent experience, he was inclined to think that secondary infections in renal tuberculosis were much more common than was supposed, the pathologist should always make careful cultural examinations for secondary infections, and this could only be done if catheter specimens were available. With regard to spontaneous healing of renal tuberculosis, Dr. T. B. Hobbs, resident medical officer at Victoria Park Chest Hospital, had recently found two cases in which there were small areas of fibrosis in the kidneys of phthisical patients, so that spontaneous healing did occasionally occur.

The PRESIDENT (Sir Holburt Waring) mentioned that he had dealt surgically with a case of what was supposed to be, on x-ray examination, calculus of the kidney, and had found a large area of healed tubercle.

Mr. JOSELYN SWAN said that a patient with a bad tuberculous kidney, and even with tuberculous infiltration in the vesicle and prostate, was a perfectly good surgical risk, and could be cured. It was astonishing how well the patients were even after heroic operations. He was inclined to put the proportion of cures considerably higher than the 60 per cent mentioned by Mr. Nitch. He was quite certain that the whole length of the ureter ought to be removed at the same time as the kidney, otherwise the operation was incomplete, leaving what was virtually a test tube of tuberculous material in the ureter. Vesicular tuberculosis was almost always secondary to renal or genital tuberculosis, but he had experience of at least one case in which there was undoubtedly primary tuberculous disease of the bladder. He thought that the less one did in the way of local treatment of the bladder the better, when the primary focus in the kidney was removed it was astonishing how the bladder condition cleared up, he had seen quite large tuberculous ulcers in the bladder scarred over.

Dr. NATHAN RAW could not agree that the mode of infection from pulmonary tuberculosis in those cases in which the kidneys were involved was through the blood stream. He thought that extension to the kidney was very often by way of the mesenteric glands. In cases of primary pulmonary tuberculosis the number in which the kidney was affected was remarkably small, but in primary genito-urinary cases the number of subsequent invasions of the lung was larger. With regard to tuberculin, he was of opinion that this extremely valuable remedy ought to be prepared from attenuated, not toxic, cultures, for the treatment of all forms of tuberculosis.

Mr. J. E. H. ROBERTS said that genital tuberculosis was a rare complication of the pulmonary condition. During the last five years at Brompton Hospital he had operated upon only twelve cases. In such operations he had as a rule removed the testis, epididymis, and cord as far as the internal ring. In the majority of such cases there were nodules also in the prostate. He had found it useful, after operation, to apply x-rays to the vesicle and prostate and to the course of the vas between the internal ring and the vesicle. The rapid disappearance of the lesion under this procedure was surprising, and he proposed to continue this treatment.

Dr. ROLF CREASY spoke of the good effects of tuberculin. It was right, as had been stated by other speakers, to begin with very small doses, and gradually to work up to large ones, but the really beneficial effects of tuberculin would not be observed until the big doses were given.

Sir HENRY GAUVAIN referred to the extreme rarity of this condition in children. Out of some 4,000 cases which had passed through his hands at Alton he could recall only two with renal tuberculosis.

Mr. NITCH and Mr. KENNETH WALKER replied briefly to some questions which had been addressed to them. The latter stated his impression that genital tuberculosis was certainly much less common in this country than on the Continent.

ORTHODONTICS FOR THE MASSES

In a paper read before the British Society for the Study of Orthodontics, on December 7th, Mr. F. ST. J. STEADMAN discussed the importance of the adequate treatment of cases of malocclusion among the poorer classes of the population. He declared that a very large number of cases of malocclusion were being allowed to develop in spite of regular attendance of patients on their dentists. The reason for this was twofold: the inability of parents to pay adequate fees for complicated methods of treatment, and the lack of training and interest taken by a large proportion of the dental profession in orthodontics. He went on to show how much could be done by means of extraction alone, in most cases without the appliances which made the treatment so prolonged and expensive. In some thirty cases which he demonstrated the results, though not always the best obtainable, nevertheless proved that marked improvement could be obtained very often by quite simple methods. He emphasized the importance of the adequate study of cases treated by extraction in view of the fact that it present a large number of cases were treated wrongly by taking out the wrong tooth or the right tooth at the wrong time, leading to severe mutilation of the dental arches. In a long and interesting discussion several leading orthodontists spoke in support of the principles advocated in the paper.

Mr. NORMAN BENNETT said that a critic might interpret the argument as meaning that it was better to do bad treatment than no treatment at all, but that would be an unkind way of putting it. It could not be considered bad treatment if the extraction of certain teeth left the child with a better occlusion than before. Apart altogether from the economic aspect, to describe every case of extraction as mutilation was absurd. Those who had seen the thousands of children who came forward in hospital practice would agree that extraction was in very many cases the only treatment practicable, but the right teeth must be extracted and at the right time. It was not a question, however, of putting extraction on the one side and treatment by appliances on the other as if they were antagonistic. At the one extreme there were cases in which obviously no teeth should be extracted at all, and which should be dealt with entirely by appliances, at the other end of the scale there were cases in which extraction was obviously called for, and in which, after extraction, no other treatment was required. But in between these two extremes there were a large number of cases in which extraction was necessary but in which treatment by appliances in addition was required in order that the best result possible might be produced. It was too often assumed in cases in which extraction was a necessary part of the treatment that extraction was the only thing that needed to be done.

Mr J H BIDCOCK agreed that regard must be had to the masses of the people who could not afford elaborate treatment, and who, of course, greatly outnumbered those who could. In such cases the second best was very much better than nothing at all the best could not be achieved.

Mr A T PITTS said that he had always held the forceps to be the most valuable weapon in the armament of the orthodontist but he agreed that the number of cases that could be treated only by the forceps was very small, and that a great number did need some supplementary treatment, although such treatment could be very much simplified if the extraction had been carried out.

Mr HAROLD CHAPMAN, president of the society, said that cases were often seen in which extraction had been performed to relieve crowding but eventually the crowding had not been relieved so that the orthodontist had to practise a good deal of caution and perhaps even to put in appliances after all in cases in which extraction was at first thought to be sufficient.

At a meeting of the Nottingham Medico-Chirurgical Society, held on November 5th with the President, Mr H BELL TAYLOR, in the chair, Sir WILLIAM WILCOX delivered an address on the treatment of diabetes with special reference to toxicæmic conditions and insulin. He expressed his belief that in a great majority of cases diabetes originated as a result of some toxicæmic condition which caused impairment of the endocrine function of the pancreas. He believed that in most cases a definite focus of infection could be found and this was often dental, tonsillar, or colonic in origin. Attention was called to the great frequency of latent maxillary antral infections these having undoubtedly been the cause of numerous cases of severe diabetes. Illustrative cases were given in detail which showed the great improvement in the diabetic condition when the focus of infection was removed. In a number of cases the condition had resulted in a cure. In conclusion, Sir William Wilcox dealt with the dietetic treatment of diabetes and the use of insulin, pointing out the precautions necessary. A discussion followed, in which the President and Drs JACOB ROWE, and CARTER took part.

Puerperal Septicæ

WITH reference to the report in the BRITISH MEDICAL JOURNAL of December 12th (p 1125) of a paper read by him on puerperal infection, Dr H J PHILLIPS wishes to point out that the treatment he described was devised by Dr Remington Hobbs and not by himself.

Reviews.

RESPIRATION IN DISEASE

Respiratory Function in Disease represents a considerable achievement on the part of the authors Professor J C MEAKINS and Mr H W DAVIES. The book is addressed to those engaged in the practice and teaching of medicine and it will be strange if amongst these it does not find a large audience. But to others engaged in the purely physiological aspects of respiration there is embodied much that is valuable. The laboratory worker is privileged for the sake of greater exactness to take his problem to pieces. He can study isolated functions. The physician must always see his patient whole. If then we do not from time to time take the stock or the relation of special research to the life of the animal normal and abnormal, continuity and confusion of thought are likely to creep in. Even the traditional language of the subject may suffer by diverging interpretation. In the present volume we have the welcome opportunity of reconsidering what we severally mean by such terms as "acidosis," "anoxemia" and "asphyxia." So successful has been the application of principles of physical chemistry to the problem of the regulation of blood equilibria and the gaseous exchange that the chemical control of respiration is capable of very exact description. What must not be forgotten is the fact that behind this presides a

physiological regulation comprising nervous, metabolic and excretory factors which have not yet been subordinated to a mathematical formulation. The authors have not failed to remind us that, though the fitness of the environment may be a chemically demonstrable fact, the control by the organism of its own response remains a physiological problem.

The book opens with a careful and not too extensive review of the recent progress in the physico-chemical of blood equilibria and the respiratory exchange in relation to functional anatomy, circulation, and metabolism. One-fifth of the volume is wisely devoted to this. Similar space is allotted to the general pathology of the respiratory function whilst the main body of the book is devoted to a consideration of the functional disturbances in specific diseases—bronchial, pulmonary and pleural lesions and cardio-vascular and nephritic diseases. In another chapter are discussed the effects on respiration of abnormal environment, mountain sickness, gas poisoning and the like whilst the chapter on therapy is largely devoted to a detailed consideration of the administration of oxygen.

There remain some hundred pages which are suitably occupied by the question of the assay of functional disturbances and physiological fitness by lung volume, vital capacity and basal metabolic rate, and to description of the standard methods of blood and alveolar air analysis. The bibliography covers four hundred original papers.

This book will find many readers, and careful readers are likely to be its best advertisement.

LOCAL IMMUNIZATION IN SOME GENERAL DISEASES

PROFESSOR BESREDEKA, in his book *Immunization Local* gives a summary of conclusions he has reached from very many years of study. The most important idea put forward is that indicated by the title. Professor Besredka believes that the reaction to some diseases is not a reaction of the organism as a whole but is confined to certain tissue or groups of tissues. He describes experiments upon the anthrax bacillus, on staphylococci and streptococci and on dysentery and typhoid bacilli. In the case of the first three organisms he considers that infection and immunization primarily concern the skin or mucous membrane whilst in the case of the last two organisms the intestinal tract is primarily affected. Professor Besredka gives a full account of his fundamental experiments upon anthrax infection. He first proved that a skin lesion was essential for the infection of guinea-pigs with anthrax and that although guinea-pigs could not be immunized against anthrax by the most prolonged hypodermic or intravenous administration of vaccines, yet partial immunity could be rapidly produced by cutaneous inoculation. These researches led to the perfecting of methods of preventing cutaneous vaccination for larger animals, which was applied with success by the veterinary service of the French army in Syria. In the period from 1919 to 1923 the average loss of horses and mules from anthrax in this army was 81 per 1,000. Cutaneous vaccination was tried on 882 horses and mules and the loss from anthrax in these animals was at the rate of only 0.45 per 1,000 per annum.

In bacillary dysentery and typhoid Besredka believes that the intestinal wall is the susceptible tissue which the invading organism attacks and that this must be immunized in order to protect the animal. He describes laboratory experiments with Shiga's bacillus and *B. typhi* and explains what he considers to be the rational vaccination by oral administration. The successes at ending the oral method of vaccination in various epidemics of dysentery are shown by statistics. In one epidemic of dysentery in a garrison of 1,100 men one-half were vaccinated and the other half not; the incidence of disease was 76 per cent amongst the vaccinated and 40 per cent amongst the unvaccinated. Figures are also given showing that oral administration of TAB is at least as effective as the hypodermic administration of this vaccine.

¹ *Respiratory Function in Disease*. By Jonathan C. Meakins, M.D. C.M. (Cant.) F.R.C.P. Edin., F.R.S. Edin. and H. Whitridge Davies, M.R.B.S. Adelaide. Edinburgh and London: Oliver and Boyd 1925. (Med. Sci. pp. x + 478. 6s. 6d. net.)

² *Immunization Local*. By Professor Besredka. Paris: A. Benoit. 1925. (Paris. Sci. pp. 252. 20 fr.)

Professor Besredka's conclusions are, of course, of the very highest theoretical and practical importance, and he has summarized the results of his prolonged researches very concisely and clearly in this book.

DENTAL AND MAXILLARY SURGERY

THE volume of *Annual Reports of the Royal Dental Hospital of London*¹ contains some eighteen articles by various members of the staff on subjects of maxillary as well as of purely dental interest. One of the most valuable deals with the perennial difficulty of so-called "dead" teeth. It is by Mr J G Turner, and wisely does he commence by saying that "the attitude of individual members of the profession ranges from claims of infallibility to confessions of total failure"; at the conclusion of his article he acknowledges that "in dealing with dead teeth we are compromising with the devil."

Mr Dolamore contributes a useful series of cases in which serious dental haemorrhage was treated by suturing the gums, this method has the advantage of avoiding the subsequent removal of plugs, a fruitful cause of recurrence of troublesome bleeding, and at the same time does not preclude the use of haemostatic drugs when deemed desirable.

An article on the clinical aspects of x-rays in dental practice is quite needlessly spoilt by a common cause of confusion in dental writings—namely, the indiscriminate use of diagrams which are sometimes negative and sometimes positive. As the practitioner is always provided with negative diagrams by the radiographer, it is surely common sense that the diagrams should represent the negatives to which his mind and eye are accustomed. On page 110 of the same article additional confusion is caused by Fig 5 succeeding Fig 3, and Fig 4 following Fig 5.

For those whose work occupies the borderland between dental and maxillary surgery these reports of the Royal Dental Hospital are well worth perusal. The book is extremely well got up and the diagrams and illustrations excellently reproduced.

ANATOMY FOR ARTISTS

THERE is good reason for supposing that the ancient Greeks knew nothing of human anatomy as disclosed by dissection, but reproduced in their sculpture only what they saw of the nude body, since the days of Michelangelo, at least, it has, however, been held by painters and sculptors that a knowledge of myology is desirable for artists. That such a knowledge may be abused the works of Michelangelo himself testify, but, assuming its desirability, Mr D Wolff's book, *Anatomy for Artists*,² can be recommended as a means of acquiring it. Judging from the title-page and jacket of the book, the illustrator, Mr George Charlton, is a follower of Albrecht Dürer. The numerous illustrations are clear and the information which they convey definite, but the art student must not assume that the appearances of dissected muscles are quite such as these, which are obviously intended to be diagrammatic or symbolical. The descriptions and illustrations of the bones are adequate.

As Mr Wolff justly claims, his representations and descriptions of the subcutaneous fat of the female are a novelty in works on artistic anatomy. In previous books such as those of Robert Knox and John Marshall the nude female form has been represented in all the alluring beauty of youth. Mr Charlton represents a rather obese woman past her youth and with her skin folds. In the profile view the posture may be typical of the average model, but it cannot be allowed to pass as the normal attitude of a really healthy vigorous woman. The exaggerated lumbar curve amounts to a distinct lordosis. There is no illustration of the nude male figure, although a comparison

of the amount and distribution of subcutaneous fat in the young adult male with that of the female might have been instructive.

SOME ASPECTS OF PSYCHOLOGY

FIVE lectures by Professor KNIGHT DUNLAP have been published in a volume entitled *Old and New Viewpoints in Psychology*.³ The topics discussed are mental measurements; present-day schools of psychology, including behaviorism, psychoanalysis, and "instinctivism"; the psychological factors in spiritualism; the psychology of the comic, and the reading of character from external signs. Attention has been given to the last subject, as it would appear that there is an increasing tendency in America at the present time to employ so-called character analysts. After a few minutes spent in interviewing an employee the "expert," having noted the characteristics of eyes, mouth, ears, hair, and shape of head, decides upon the general mental and moral characteristics of his subject, and upon the particular line of work, if any, in the factory to which he should be put. Such methods must tend to bring industrial psychology into disrepute.

In his discussion of the psychology of the comic the author develops the view that a situation provoking laughter is always one which enhances an individual's appreciation of his own superiority. This theory, which scarcely seems adequate to account for all the subtleties of wit and humour, would appear to be similar to that propounded by Thomas Hobbes (quoted by Dr William Macdougall), who traced the source of the pleasure responsible for laughter to the feeling of "sudden glory," which he supposed all men to experience at seeing another man cast down. The author of the work before us is severely critical of behaviourism, and still more so of psycho-analytic theory. He is unable to discover that Freud and his disciples have hitherto contributed anything of value to psychology.

NOTES ON BOOKS

THE eighty second annual issue of the *Medical Directory*, for 1926, has been published by Messrs Churchill.⁴ Minor changes have been introduced here and there in the introductory and supplementary sections, but in general the new volume is arranged and printed in the familiar form which has made it so valuable a reference book to generations of medical practitioners. As daily, and we might say hourly, users of the *Medical Directory*, we can testify perhaps better than others to the very high standard of accuracy maintained by this publication. The number of names in the present edition is 51,153, which exceeds that in the previous issue by 1,802, it is greater than that in the issue for 1916 by 8,583. There is again an increase in all areas, but once more a slight decrease in the section devoted to the Services, whose total has dropped to 3,283 from 3,318. The names grouped under London have grown in number by 198, in the Provinces there has been an increase of 737, in Wales of 209, in Scotland of 312, in Ireland of 169, and the miscellaneous section headed "Abroad," which includes medical men and women registered in this country and residing in the Dominions, has grown by 412 names. Of the work as a whole we may say that editorial care and experience, with the support and co-operation of the profession at home and abroad, has produced once again a yearbook which is a model of its kind.

M JAQUEROD'S little monograph on *Haemoptysis in Pulmonary Tuberculosis*⁵ has been translated into English by Dr S F SILBERBAUER. The ideas expressed in the book are the fruit of twenty years' experience, and as such are entitled to respect.

The eleventh edition of *The Nurse's Dictionary*⁶ has been considerably enlarged, and the text has been revised and brought up to date. Besides providing a dictionary of medical terms and nursing terms, explanations are given of the abbreviations of medical terms used in prescriptions, tables of weights and measures are also supplied.

SATURDAY, DECEMBER 19TH, 1925.

RESPIRATION

It is an axiom of medicine that a sound pathology rests upon a sound physiology. At the same time, it is to be acknowledged that there is mutual benefit in a close liaison between clinic and laboratory, for it is in the diseased organism that we are permitted to watch Nature perform many of the more critical experiments in physiology. There is frequent need, therefore, that there should be performed the important service of bringing into a common discussion the problems of the normal and of the abnormal. In *Respiratory Function in Disease*—which we review on another page—Professor Meakins and Mr. Davies make of this service a considerable achievement. They offer a careful account of progress in a field which is difficult and forbidding to those who had hoped to have left far behind them the subtleties of physico-chemical argument. The thorns have been cleared as far as may be from a path that leads by way of partial pressures, electrolytic dissociation, and—that blessed symbol— pH , to an understanding of the chemical regulation of respiration in health and in disease.

No problem in physiology has submitted to such exact expression in mathematical terms as has that of the gaseous exchange and the electrolyte equilibria of the blood in respiration. So smoothly runs the story of the chemical regulation of the respiratory function that we are tempted to forget that thermodynamic arguments take little count of physiological mechanisms, and that we still have far to travel before we obtain a comprehensive picture of the biological mechanisms of the respiratory function. After all, the intimate nature of a process is likely constantly to be stated in new words as the comprehension of matter extends and the language of science grows in harmony. To the practical mind the quantitative analysis of the function is the great achievement. Having numbered and weighed the components, and having measured the effects of change in the environment, the function is placed substantially under control. Sound practice rests upon control.

Two articles in our present issue deal with the control of respiration under conditions of great interest to clinical medicine. One is a lecture by Professor Yandell Henderson—a welcome visitor to this country—on the subject of respiration in anaesthesia. The other reports a discussion on the same subject at the Anaesthetics Section of the Royal Society of Medicine. The contributors to the discussion were Dr. Shipway, the President of the Section, and Professor Pembrey. The anaesthetist and the experimentalist pool their experiences and views on the practical control of respiration in anaesthesia. Throughout the discussion recurs the theme, which is the special text of Professor Henderson's lecture, of the control of breathing by carbon dioxide. The reader, who may remember only that he was taught that carbon dioxide was the waste product of animal metabolism, of use merely for the charitable purposes of plant life, will

marvel at the great respect now being paid to this "inert" gas. Nor is he likely to be reassured by being told of the peculiar fitness of carbonic acid, as a weak acid, for the control which it exercises over the ionic equilibrium of the blood. Let us rather hand him over to the persuasive words of Professor Yandell Henderson.

If, as Professor Henderson urges, the wise administration of carbon dioxide and oxygen makes possible the rapid initiation, certain control, and speedy removal of the required depth of anaesthesia, he will have the sympathetic ear of both surgeon and anaesthetist. If the distressing symptoms of post-anaesthetic nausea, cyanosis, acapnia, and pneumonia are also mitigated, much anxiety will depart from the operating theatre. Carbon dioxide will then hold its place as the practical controller of respiration, not only in anaesthesia, but also in gas poisoning, post-natal anoxaemia, and intoxication, and we shall agree with the chemists that the animal exercises a nice discretion even in the choice of its waste products.

Did not Elshah employ, with complete success, the method of mouth to mouth insufflation in the resuscitation of the son of the Shunammite woman? A prophet indeed.

BLOCK GRANTS FOR HOSPITAL SERVICES

At a meeting of the Midlands Branch of the Incorporated Association of Hospital Officers, held in Birmingham on December 12th, an important speech on voluntary hospitals was made by the Minister of Health, the Right Hon. Neville Chamberlain, M.P. The association which he addressed contains a very large number of hospital secretaries and other important hospital officers, mainly those who are connected with the voluntary hospitals. In his speech to the association the Minister of Health gave most eloquent and ungrudging testimony of his appreciation of the work done for the health of the community by the voluntary hospitals. He recounted the crisis that had come to these hospitals shortly after the war, when prices and costs rose to such unprecedented heights, and also added his tribute to the manner in which the hospital managers had surmounted this crisis, and secured, for a time at any rate, the effective work of the voluntary hospitals. Thus, he said, was a demonstration of the inherent vitality of the voluntary system and the hold that it had upon the affections of the people. But, he added, new times brought new problems. The present problem was one which dealt with the necessary increase of the voluntary hospital accommodation. The growth of population made an increase imperative. If the maintenance of income on the present scale was difficult, how were the increasing demands for capital expenditure to be met?

The ideal scheme of hospital services would bring into co-operative relation all the hospital accommodation and work of the country. In such a scheme the voluntary hospitals must necessarily play a great part, and Mr. Chamberlain suggested that a system of "block grants," analogous to that of which so much had recently been heard in relation to educational services, might well be found applicable to public health work and hospitals. It would necessitate the establishment of hospital areas throughout the country, for each of which there would be a controlling body to take into consideration all the hospitals therein and the needs for extension. Certain measures of control would necessarily follow such procedure, the authority would need to have its say as to what, if any, exten-

sions were contemplated, and to have some voice in the settling of the site, and perhaps in the character of the buildings. The control would be applicable to every type of hospital, whether statutory or voluntary. The body should be fully representative, both of statutory authorities, voluntary hospitals, and of the medical profession. The block grant would be a return for the exercise of general authority over the main lines of policy. It would be for hospital expenditure, and would be for a definite amount to be expended over a term of years, subject only to the conditions indicated and to the maintenance of a certain minimum standard of efficiency. Subject to that, each hospital would have absolute freedom in administration of its own affairs. In this way it would be possible, Mr. Chamberlain thought, to secure the increased accommodation necessary, to preserve the voluntary hospitals, and even enhance their value, and to do so at a minimum cost to public funds.

It will be remarked by those who have made themselves familiar with the work of the British Medical Association and its hospital policy (which has been formulated after exhaustive discussion in the Divisions and the Representative Body during the last half dozen years, and of which a very clear account is given in Dr. Anderson's address printed in this week's SUPPLEMENT) that the scheme outlined by the Minister of Health is in very close conformity with the Association's policy. Both envisage the formation of hospital areas, the co-operation of all types of hospitals within each area, the prevention of overlapping, and the determination and general control of extensions, and all this without interfering with the autonomy of the several types of hospitals in their domestic affairs. Each institution would be encouraged to develop on the lines of individual initiative. When the Association gave evidence before the Care Committee on the voluntary hospitals it advocated that these hospitals during the crisis should be sustained on the plan adopted in respect of the universities through the University Grants Committee. That was done, and most successfully, and without any infringement of the vital independence of the hospitals. That the same is true of the arrangements for the universities was made clear by Sir Gilbert Barling, who spoke for Birmingham University at this meeting in Birmingham. This system, which now goes by the name of "block grants," provides a buffer authority between the subsidizing State and the beneficiaries. To this authority is given the responsibility of determining when, to whom, in what manner, and in what amount grants shall be made. This plan possesses the very great advantage that it is possible to remove such vital and sensitive services as those for higher education and hospital provision from the risk of injury entailed by the turmoil of electoral strife.

We hope that the Minister of Health may be able to initiate this scheme and see the effective beginning of the work during his term of office, and add yet another measure of constructive statesmanship to those he has already achieved.

EPSOM COLLEGE

SIR HUMPHRY ROBERTSON, speaking as a guest at the Old Epsomian dinner on December 10th, observed that the services rendered to the medical profession by Epsom College had now become so valuable that they might almost be described as essential, and he added that the profession was not unmindful of the debt it owed the College, for it had shown its appreciation in

some measure in the past by personal subscriptions, legacies, and the provision of certain scholarships. It is now evident that this recognition of indebtedness is extending, and, in his letter of appeal, which appears at page 1197, Dr. Raymond Crawford, chairman of the council of Epsom College, reports a gratifying increase in annual subscriptions from medical practitioners, and also in the active support given by Panel Committees throughout the country.

Epsom is the only public school closely associated with the medical profession, and it is estimated that at present some 150 Epsomians are students at various hospitals, while a large proportion of the old boys now at the universities are taking the medical curriculum. We have previously remarked on the high standard of the preliminary medical training in the school, and it may now be added that the new chemistry block, to be completed next summer, will be one of the finest of its kind in the country, it will have accommodation for 110 boys, and represents an anticipated enlargement of the College itself. A hint of this enlargement is to be traced in that part of Dr. Crawford's appeal where he refers to the suggested building of a new infirmary. This urgently needed addition would set free the present building, which, though ill adapted for medical treatment on modern lines, would provide housing for forty-five more boys. Since many of the 500 boys on the present waiting list for entry at the College are the sons of medical men eager to follow their fathers in the work of our profession, this portion of the appeal should arouse special interest. The greater economy in management made possible by the erection of this new infirmary, and by the increase in the number of boys, would lend automatically to further extension of the advantages to individual medical practitioners with sons to educate, while in view of its high efficiency and great popularity, enlargement of the school may be expected to benefit the medical profession as a whole.

Details of the College education and of the Royal Medical Foundation appear in our advertisement pages this week, and we may remind our readers of the statement made last year—that, great as are the needs to be met, yet if one of every two medical practitioners contributed a guinea annually for five years the Medical Foundation at its present dimensions would be permanently endowed. The great work of the foundation in helping members of the medical profession who have fallen on evil days, in assisting the widows of those who have died without being able to make provision, and in educating their sons to follow their high calling, must command our respect, but it is still sadly inadequate to meet present needs. We therefore commend Dr. Raymond Crawford's appeal to the generosity of our readers in the hope that the next annual report may reveal a further advance and foreshadow still greater appliances—such as means prevent them from being supplied for the treatment of as many abdominal belts and think that small gifts of included belts and pads for the Association would contribute to so-called floating or through the Association would preponderance of these for the committee, the additional, and the question suggests itself how would go far to the right kidney to digital palpation in the appeal. I have no right kidney to digital palpation welcome, but cannot follow. Whatever may be thought of stream. There is, to doubt that many patients get educational work of E. Other large items in the list of activity of its Medical and artificial teeth, 2,310 complete upon an increasingly subscribers.

PROFESSOR REID OF ABERDEEN

In the *Aberdeen University Review* for November, Sir Arthur Keith has an appreciation of the work of Professor Robert Reid, who retired last September from the chair of anatomy in Aberdeen after filling it for thirty-six years. Professor Reid was the third son of the Rev. William Reid, minister of Auchendou on Donside, and received his early education at the neighbouring village school of Lumsden. He came of a family which had had its home for many generations in the North of Scotland, and which had contributed distinguished representatives to the church, the army, and to the fields of literature and invention. One of Professor Reid's brothers was the late Dr. William Reid, medical superintendent of Aberdeen Royal Asylum, and another was Major-General Sir Alexander John Reid. Two of his schoolfellows in the village school at Lumsden were the late Sir William Robertson Nicoll and Dr. Henry Stephen, professor of English literature in the University of Calcutta. At the age of 15 Robert Reid proceeded for a few months to the Grammar School at Aberdeen, and later went to King's College. The winter session 1868-69 saw the commencement of his medical studies at Marischal College, where John Struthers was then professor of anatomy, a subject to which from the first Reid was attracted. He graduated M.B., C.M. in 1872 at the age of 21, and after holding the post of house-physician at the Royal Infirmary commenced his career as an anatomist, by becoming assistant to Professor Struthers. In 1873 he accepted the appointment of demonstrator of anatomy in the medical school of St. Thomas's Hospital, London. In 1877 he became joint lecturer and then senior lecturer. When Robert Reid entered St. Thomas's Hospital in 1873 anatomical inquiry had come under the dominance of Darwin, and variations in structure which occur so abundantly in dissecting-room subjects had taken on a new significance and importance. Into this field he entered with zest, and in 1884 opened up a line of research in which he had no equal. In 1884 he published an article dealing with the relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp. This, Sir Arthur Keith declared, placed him in the front rank of the anatomists of his time. Operations on the brain were then in their infancy, and surgeons needed a simple, accurate, and reliable method to guide them to its various parts. This method of research entailed much exact observation and systematic records, but it is a contribution to practical knowledge, not to theory. In 1889 he published a paper of similar nature dealing with the spinal cord, which has been in great part embodied in surgical and anatomical textbooks. When the Anatomical Society of Great Britain and Ireland was founded in 1887 Robert Reid became one of its original members and was elected a member of its first council. In the autumn of 1889 Professor Struthers retired from the chair of anatomy at Aberdeen, and Robert Reid was presented to this Regius chair by the Secretary for Scotland, the next thirty-six years his work. Henderson—a welcome addition to the subject of respiration, and included details of other reports a discussion on the subject of respiration. The contributors to the discussion, enriched anthropological The President of the Section, a, He greatly developed The anaesthetist and the experience of his predecessor, experiences and views on the subject of respiration in anaesthesia. The importance of respiration in anaesthesia. This subject. In 1896 he Professor Henderson's lecture, breathing by carbon dioxide, resulted in a record, remember only that he was taught the physical and renal was the waste product of animal attending the University merely for the charitable purpose of exact measurements.

and details of growth of 2,000 students drawn from the population of the north-east of Scotland. It has proved of immense importance in anthropological science, and mention may be made of Professor Reid's papers drawn from it, upon the relation of cranial capacity to intelligence and on the relation between stature, head breadth, and head length of 847 natives of north-east Scotland, and his anthropometric comparison between natives of the north-east of Scotland and inhabitants of Norway and Sweden. These papers appeared in the *Journal of the Royal Anthropological Institute* for 1923 and 1924, and in the third of them the question is answered as to the race to which the Aberdonians belong, the answer being that they are of a common stock with the Scandinavians, and have little or nothing to do with the Mediterranean race nor with the dark-haired, round-headed Alpine stock. Professor Reid also made valuable investigations into the relationships of the bones found in several ancient tombs in Aberdeenshire, which were contributed to the *Proceedings of the Society of Antiquaries of Scotland* and other publications. In 1912 Professor Reid published an illustrated catalogue of the anthropological museum at Marischal College, University of Aberdeen, in which this valuable collection is described, and in 1924 he added an illustrated catalogue of specimens from prehistoric interments in Scotland, wherein is set down all that is known of the strange people who lived in Aberdeenshire some three or four thousand years ago. His valuable work for practical surgery, which has already been mentioned, was completed during the war by an exact description of the position of the nerves in the limbs, which was published in the *Journal of Anatomy*.

HIGH BAROMETER AND SUDDEN DEATHS

In a note in our issue of December 5th (p. 1098) a correspondent ("A O W") mentioned the association of high barometric readings in the second half of last November with an unusual number of deaths from "heart failure." The point thus raised in a brief and tentative manner has drawn from Dr. Percy Stocks, medical officer to the Department of Applied Statistics and Eugenics in the University of London, an interesting communication. It seemed to him, he writes, that it might be worth while to ascertain whether any statistical evidence for such an association could be obtained. He has therefore correlated the weekly deaths registered in London as due to diseases of the heart and circulatory system with the mean corrected barometric pressures for the same weeks at Greenwich during this period of the year since 1900. The figures used were those given in the weekly returns of the Registrar General for the last week in October and the four weeks of November for the years 1900 to 1914 and 1919 to 1925. Dr. Stocks finds that the resulting correlation coefficient is 0.23 ± 0.06 , which indicates an appreciable relation between deaths from circulatory diseases and the atmospheric pressure. Since (he continues) a high barometer in November is frequently associated with a low temperature, which is known to increase mortality from circulatory diseases, this might be the real explanation, but to test this possibility the correlations have also been calculated with the mean temperature of the air at Greenwich for the same weeks. When this is done there is a coefficient of -0.44 ± 0.05 between deaths from circulatory diseases in London and mean temperature, and of -0.15 ± 0.06 between mean barometric pressure and mean temperature. It follows from these figures by partial correlation that when the effect of temperature is eliminated mortality is still correlated with barometric pressure to the extent of 0.19 ± 0.06 —that is to say, there does appear to be a small but significant relation between heart deaths and

¹ Defined as the week ending on one of the dates October 28th to November 3rd inclusive.

atmospheric pressure during November apart from the effect of temperature, a result which seems to confirm the opinion formed by "A O W." Dr Stocks adds that the mean weekly deaths from circulatory diseases in the twelve weeks preceding New Year's week (that is, the week containing New Year's day) for the last twenty-five winters were as follows: 154, 161, 164, 168, 180, 190, 193, 201, 197, 196, 195, 187, the highest figure (201) being for the fourth week in November. The drop in the last figure is, he says, probably due to some peculiarity in registration returns during Christmas week, since the next, New Year's week, gives the figure 224, the figures for the ensuing twelve weeks are then 212, 213, 201, 208, 215, 221, 215, 206, 202, 204, 196, 196. Dr Percy Stocks's conclusion, therefore, is that there appears to be in the average year a rapid rise in mortality from circulatory diseases during November, a slight fall during December, and another rise about the New Year, the highest mortality for the year being in January and February.

THE TSETSE FLY PROBLEM

The solution of the tsetse-fly problem is one of supreme importance to tropical Africa, not only on account of the losses in stock due to *n'gana* and other trypanosome diseases, but because of sleeping sickness in man. Many schemes for the eradication of this insect have been suggested—trapping, cutting down undergrowth, and so on. A method which has been popular with many people is the suppression of the wild game hosts and the consequent starvation of the fly. The Society for the Preservation of the Fauna of the Empire is among the individuals and bodies which have protested against this policy, and has recently issued a pamphlet urging that, should extermination of game be necessary, it must be discriminate, and pointing out that epizootics of rinderpest have killed out game in parts without also destroying the fly. It is suggested also that from wild game it may be possible to obtain an immune serum for use in stock. The object of the society, however, is mainly to preserve the big game, and much capital is made of the monetary value of these animals to the African colonies. While we cannot agree that the value of game to the sportsman should have any influence on the fight against trypanosome diseases, yet we agree that it would not be advisable to exterminate game without fuller investigations, such as those Mr Swynnerton is carrying out. Cattle definitely carry the human parasite, and in them it causes a chronic condition. The situation has not been fully explored yet, but in any event history shows that to tamper with the balance of nature is at best a hazardous task, and (as Australian rabbits and American sparrows have shown) may be followed by unexpected consequences.

INSURANCE AGAINST DOCTORS' BILLS

The Family Medical Services, Ltd, is a company which issues a Lloyd's policy, described in the *BRITISH MEDICAL JOURNAL* on September 26th last, for insuring against the cost of doctors' bills. We found this experiment in middle-class medical insurance interesting and ingenious, and apparently it has already been sufficiently successful to justify some reduction in terms. Under the scheme the head of a family insured all the members of the family who were eligible against the medical fees payable during the year, after a deduction which varied according to the doctor's fee and the size of the family. Under another table a proportion of the expenses of operations and nursing homes could be covered. Insurance under Table A applied only to general practitioners' fees, whether 7s 6d, 10s 6d, or £1 is a visit. This table has now been modi-

fied, so that bills for fees of 5s can be covered, and the amount of the bill payable by the insured is now £2, £2 10s, £3 10s, or £7, according to the size of the doctor's visiting fee, together with a fixed sum for each insured person over the number of two. The company (whose address is 20, York Street, Manchester) has issued a leaflet answering some of the points of doubt or difficulty which were raised about the scheme. It has also omitted neurasthenia from the list of diseases excluded from benefit.

THE SURGICAL AID SOCIETY

THE Royal Surgical Aid Society attained its grand climacteric last week, when the Lord Mayor presided over its sixty-third annual meeting at the Mansion House. Beginning in a small way in 1862, this society has steadily increased in financial strength and philanthropic effort until in the year ending in September last its income amounted to £42,000. Although a subscriber's letter or letters are generally needed to entitle applicants to relief, the committee is able, out of funds placed at its disposal, to help patients who require costly or elaborate appliances by the grant of letters, and the honorary surgeons are empowered to recommend the supply of urgently needed instruments, such as trusses, without the production of letters. From the very beginning it has been a fundamental regulation of the committee of this society that no appliance shall be supplied except on the prescription of a registered medical practitioner. It was long ago found, however, that many patients had difficulty in obtaining such a prescription, and applied directly to the office with a subscriber's letter only. To meet the needs of these, honorary surgeons were appointed whose duty it is to examine such cases, make a diagnosis, and prescribe the requisite appliances. At present there are three such honorary surgeons, who are all orthopaedic specialists attending at the head office in London, while each of the eighteen country branches, scattered over the provinces from Cardiff to Colchester and from Sunderland to Hastings, has an honorary surgeon on its staff. In the last year nearly 7,000 patients were thus examined at the London office alone, while in London and the provinces taken together, according to the surgeons' report, 22,000 cases were dealt with and over 30,000 appliances provided. Nearly 4,000 of these patients were suffering from inguinal and femoral hernia. The latter form was found in only 1.32 per cent of the 3,385 male cases, but in 18 per cent of the female ones. This is a very much lower percentage than that given in some well known works on hernia, and it is difficult to account for the discrepancy. The honorary surgeons advocate the radical cure of hernia in suitable cases, and are provided with leaflets explaining its desirability, for distribution to patients, but it is found that not many are ready to accept this suggestion, no doubt largely owing to the length of time necessary for true radical cure and their fears of thereby losing their employment. Most patients whose ruptures can be kept up with trusses are content with them. Over 3,000 appliances—stockings and bandages of various kinds—were supplied for the treatment of varicose veins, and nearly as many abdominal belts and supports. Among these are included belts and pads for the relief of the symptoms attributed to so-called floating or loose kidney. The great preponderance of these for the right side only is notable, and the question suggests itself whether the diagnosis does not often depend on the greater normal accessibility of the right kidney to digital palpation as compared with its fellow. Whatever may be thought of the possibility of supporting a loose kidney by means of external pads, there is no doubt that many patients get relief from their use. Other large items in the list of appliances are spectacles and artificial teeth, 2,310 complete

or partial dentil prostheses were supplied in the year under notice, in most cases on account of dyspepsia attributed to defective teeth, while the number of artificial limbs ordered amounted to nearly 600. Were it not for this and some kindred societies the after-care of hospital patients and the surgical care of the non-legal poor could hardly be effected unless the State shouldered the responsibility, and the Surgical Aid Society may therefore be reckoned as an important link in the chain of the voluntary hospital system.

SOCIETY OF APOTHECARIES

The winter lively dinner of the Society of Apothecaries of London was held in the Society's Hall, Blackfriars, on Tuesday, December 15th. The members of the Society and their guests were received in the Court Room by the Master (Dr T. Vincent Dickinson) and the Warden (Dr Alfred Hepburn and Dr R. W. Statham), and dinner was served in the Livery Hall. After the loyal toast had been honoured in the traditional manner, Dr Hepburn, Senior Warden, proposed the health of the Royal Navy, Army, and Air Forces, paying high tribute to the work of the services and their medical departments, and ending with some pertinent questions regarding their equipment for future needs. Surgeon Rear-Admiral Sir Percy Brissett-Smith replied in a very graceful speech on behalf of the senior service. Lieut-General Sir William Leishman, Director-General A.M.S., explained that in the absence of Air Commodore David Munro, head of the R.A.F.M.S., he was responsible for two-thirds of the reply to this toast. He said that all the services were now going through very difficult times, but the medical branches knew they had done good work in the war and were doing good work now; they were confident they would not lose the support and backing of the civilian profession. The toast of the Royal Colleges was proposed by the Master. After mentioning the seventeenth century squabbles between apothecaries and physicians—a feud largely composed by the wit of a physician-poet, Sir Samuel Garth—Dr Dickinson pointed to the harmony that had now long existed between the Colleges and the Society. Sir John Rose Bradford, Senior Censor of the Royal College of Physicians of London, said it was always a pleasant duty for representatives of his College to meet in that ancient hall and enjoy the hospitality of a medical corporation set up by James I. less than a century after the foundation of the College by Henry VIII; he paid a tribute to the Society's great services, both to the public and to the profession. Mr. Walter Spencer, replying as Vice-President of the Royal College of Surgeons of England, spoke of the important recent developments in the Huttonian Museum at Lincoln's Inn Fields, and of the debt owed by that great collection to the genius of its present curator, Sir Arthur Keith. The health of the guests was proposed by the Junior Warden, Dr Statham, and responded to by Sir D'Arcy Power. A good programme of music, provided by a quartet of singers, added to the enjoyment of everyone. The dinners of the Society of Apothecaries have the peculiar charm of a medical gathering held in the old-world setting of a city company's hall.

WILLIAM CADOGAN, M.D.

SPECIALISM is sometimes regarded as a feature peculiar to the quite modern times within the memory of many not yet on the shelf, but in the period of the commencing decadence in the medicine of ancient Egypt each disease had its physician, who was, so to speak, a strict monogamist. Passing to much later times, it is not without interest to notice as a double-barrelled specialist William Cadogan (1711-1797), who wrote "An Essay upon Nursing and the Management of Children" (London, 1750), which went

through nine editions in twenty years, and "A Dissertation on the Gout, and all Chronic Diseases, jointly considered, as proceeding from the same Causes, What those Causes are, and a rational and natural Method of Cure proposed. Addressed to all Invalids. Quod petis in te est." By a Doctor. Works were printed in London, the first in 1750, the second in 1771. Offered at the modest price of 6s. 6d. and 1s. 6d., in two years no fewer than ten editions of the "dissertation" were called for. In appearance, indeed, caused a sensation, and around a number of satirical tracts, such as a readable anonymous "Candid Enquiry into the Merits of Dr Cadogan's Dissertation on the Gout," which, incidentally, was three times the length of the original. The great Dr Samuel Johnson gave it his praise, especially for its recommendation as to moderation in diet. Professor John Rubrah of Baltimore has reprinted from the *Annals of Medical History* his article "William Cadogan (His Essay on Gout)" in an attractively got-up booklet, in which after some historical details about Cadogan, who, though a dubitable man, on one occasion teased and tormented damned champagne, this effort on gout is reproduced and appropriately supplemented by the poetical squib, "The Doctor Dissected or Willy Cadogan in the Kitchen. Addressed to all Invalids, and Readers of a late Dissertation on the Gout, etc. By a Lady. The best of all Doctors is sweet Willy O!" (London, 1771). The frontispiece of the volume is a reproduction of the portrait of Cadogan in the Royal College of Physicians of London, of which he was a Fellow, and shows that he was a handsome man. In spite of his rather popular appeal, Cadogan held high office at the College, being Harveian Orator on two occasions, when 53 and 80 years of age, a censor and elect. His personal hygiene was suspected not to come up to the standard he set up for others, but the late Dr J. T. Parry failed to find evidence of this. Cadogan, however, was no fanatic, for while asserting that "wine undoubtedly produces nine out of ten of all the gout in the world," he modestly adds that if a man adopts a proper regimen "he may safely indulge once a week, or perhaps twice, with a pint of wine for the sake of good humour and good company, if they cannot be enjoyed without it. For I would not be such a churl as to forbid, or even damp, one of the greatest joys of human life."

ANIMAL RESEARCH IN EDINBURGH

THE science of genetics, although one of the youngest branches of biology, is every day becoming more and more important. Although the subject has received more attention in America than in this country, one of the most fertile of the research stations is that in Edinburgh under the directorship of Dr F. A. D. Cren, whose fifth annual report, for the year ended March 31st, 1925, has recently been issued. The pioneer work being undertaken by that department is becoming more apparent every year. Not only is the amount of research increasing, but teaching and lecturing are playing a larger part in the activities of the department. The teaching alone makes considerable call on the time of the staff, for, in addition to five courses in Edinburgh University (one of which, we are glad to note, is given to medical graduates), courses are also given to agricultural students at Glasgow and Aberdeen. Nearly thirty lectures were given to outside bodies during the year—significant evidence of the increasing popularity of the science of breeding and its implications. The research work is concerned, mainly, with problems affecting the domestic animals and birds, but as the interest in the subject increases so also will the opportunities for further extensions.

William Cadogan (*His Essay on Gout*), by John P. Birch, M.D. New York: Paul B. Hoeber, Inc. 1925. (Cr. 8vo pp. vii + 114) 1s. 6d.

THE RELATIONSHIP OF THE MEDICAL PROFESSION TO UNQUALIFIED PRACTICE

DISCUSSION BY THE MARYLEBONE DIVISION

A LARGELY attended meeting of the Marylebone Division was held at the British Medical Association House, Tavistock Square, on December 9th for a discussion on the relationship of the medical profession to unqualified practice. Lord Dawson of Penn presided. It had been hoped that the Attorney General, Sir Douglas Hogg, M.P. for Marylebone, would be present, but his wife regretting that important duties detained him at the House of Commons.

The Functions of the General Medical Council

SIR HOLBURN WARING, Senior Treasurer of the General Medical Council, said that he was honoured by the invitation of the honorary secretary of the Division, Dr Spurgin, to open the discussion, the more so because he was not a member of the British Medical Association, he had resigned his membership some years ago in order to discharge with more freedom his duties on the General Medical Council. He began by reading the Warning Notice of the Council in regard to "covering," an offence which the Council looked upon with extreme disfavour. Any registered medical practitioner who employed an unqualified person in the sense of "covering" was liable to have his name erased from the Medical Register, but the present position of legislation was such that, although a medical practitioner could not employ an unqualified partner or assistant, an unqualified person might practise his profession independently if a misguided public chose to avail itself of his services. The main disabilities of the unregistered practitioner were inability to sign death certificates, to give evidence in a court of law on medical subjects, to recover fees in court for professional services, to sign certificates or notifications in respect of disease, and to obtain dangerous drugs under the regulations of the Dangerous Drugs Act. Many unqualified persons, nevertheless, contrived to carry on forms of practice, but, of course, they were able to make use of advertising and canvassing, which were not open to the qualified and registered. Occasionally, while an unqualified practitioner was treating a patient, some serious or possibly fatal condition developed, and a qualified practitioner was called in. In such circumstances the latter ought to refuse actively to co-operate with the unqualified or to sign the death certificate.

The first function of the General Medical Council was to maintain the Medical Register, which must not be confused with the Medical Directory. By the latter and by large numbers of the profession the Medical Directory was looked upon as an official publication, and the inclusion of a name therein was held to make a reference to the Register unnecessary, but there was one notorious case in which the name of an unregistered practitioner remained in the Medical Directory for twenty years or more, and only when the practitioner was granted the O.B.C. for his services was it discovered that he had never been on the Register. No very serious penalty was provided for this offence, and the practitioner, electing to be dealt with summarily, was fined the maximum of £20, and, of course, resigned his appointments, afterwards becoming, Sir Holburn Waring believed, a practitioner in medical electricity. Another function of the General Medical Council was to ensure that the courses of study and examinations of candidates by the licensing bodies were satisfactory, and, again, it had to see that the persons placed on the Register maintained the necessary standard of professional conduct. Practitioners were summoned before the Council mainly in two ways—one as a result of a report from the judicial authorities of conviction for felony or misdemeanour, and the other as the result of a complaint from some individual or body of persons. Many people asked why the Council did not investigate the supposed delinquencies of particular practitioners.

The answer was that, according to British justice, it was not right for one body to be judge and policeman. It was not the duty of the Council to forage around to discover malpractice, but when complaints were made it had to investigate them and, if necessary, to take penal action. The penalties it could impose were, unfortunately, limited in number. The Council might find the accused guilty of "infamous conduct in a professional respect" and proceed to erasure, in other cases, where the charge was proved, it might be held not sufficiently serious to merit the extreme penalty, and judgement might be postponed for six or twelve months, the offender being required at the end of that time to furnish evidence from his colleagues that he had been carrying on a strictly ethical practice. With regard to restorations, there was also some confusion in the public mind. It was asked why the Council did not restore a particular man to the Register. The fact was that it had no jurisdiction. The man in question had never applied for restoration, and, moreover, the two licensing bodies concerned had taken away his diplomas, and the Council could not place on the Register a man who had been so deprived. It had been complained that a man erased from the Register had no right of appeal. That was no fault of the Council, it was part of the statute, but what a man could do was to apply at a later period to the Council itself, and if his conduct in the meantime had been satisfactory and his original offence was not too heinous, the Council would probably restore his name. In conclusion, he referred to the position of dentists under the Act of 1921, the result of which had been to make dentistry a closer profession than medicine, for no one (except a registered medical practitioner) could now practise dentistry unless his name was on the Dentists Register. On the other hand, a dentist, if struck off the Dentists Register, could appeal to the High Court, a course not open to the medical man.

At the close of his address Sir Holburn Waring answered a number of questions. He stated that a very large proportion of complaints, of a frivolous character, were dismissed under the machinery of the Council without coming up for formal hearing by the full body. Motoring offences were rather new, and the number of convictions against practitioners was so small that no particular procedure with regard to these had been formulated. In the case of drunkenness it was usually only after a second or third conviction that the practitioner was summoned before the Council. Even then, given satisfactory assurances, the charge might be dismissed, but if there were still further convictions the Council might take a very serious view. In reply to another question, he said that complaints were considered only from the point of view of their substance and gravity, and no difference was made between offenders in high positions in the profession and those in the rank and file. Asked how his statement that there was no appeal from the Council could be reconciled with the statement made by the Minister of Health that an appeal could lie with the Privy Council, Sir Holburn Waring said that if a licensing body was found by the General Medical Council to be deficient as regards its examinations and what it exacted from students, and was reported by the Council to the Privy Council, the body so indicted had a right of appeal to the Privy Council.

A Review of Unqualified Practice

DR C. O. HAWTHORNE expressed the thanks of the Division to Sir Holburn Waring for opening the discussion. This was not the first request that the Association had made to him, and in view of his goodwill it would not be the last. Unqualified practice undoubtedly existed and sometimes was thrust upon the general attention in a very conspicuous fashion. Hence it was a reasonable expectation on the part of the public that the profession should declare its attitude. Personally he was disposed to think that the right kind of policy would not be reached by considering the merits or demerits of the various forms of unqualified practice. The alleged triumphs of unqualified practice, just like the alleged errors or ignorances of the qualified practitioner, naturally attracted the enterprising journalist, and these things were fairly frequent topics of conversation in the railway carriage and at the tea-table. Such stories, however, were told in

sensational terms, and the accuracy and knowledge which were necessary to a confident and scientific conclusion were generally conspicuous by their absence. It might be allowed, without any shamefacedness, that qualified practitioners, being human, were liable to err, and in individual cases did err, in dealing with the complicated problems presented to them. Equally it might be allowed that the unqualified practitioner did at times seem to secure a triumph over obstacles which for some reason or other had baffled the efforts of the qualified. But in making these admissions it was necessary to add certain comments. The first was that coincidence had a long arm and that *post hoc* was not necessarily *propter hoc*, though he would not suggest that the benefit of this natural law was reaped entirely by the unqualified practitioner. A second comment was that winning tricks was not always proof of good play, and a third, that whereas the daily routine beneficent work of thousands of practitioners throughout the length and breadth of the land in the homes of the people excited no particular remark and led to no advertisement, the triumphs—if such there were—of the unqualified practitioner were sounded forth on every hand, while his failures or the disasters which might follow his practice were generally written in water. Further, if unqualified practice were taken as a whole, from the practitioner who was boomed periodically in a society journal to the arrant quack of the market-place, or the still less attractive announcements in the advertisement columns of the Sunday newspapers, and its promises were contrasted with its performance, every impartial man would admit that these promises were, to put it mildly, grossly exaggerated, and that in particular instances there was more than a suspicion of fraud. If regard were paid to the history of unqualified practice—not merely the phase which it presented to-day, but its history over a long period of time—the admission must be made that unqualified practitioners had very often been proved to be lime-brained enthusiasts, sometimes clever commercial speculators, and sometimes deliberate frauds. Speaking generally, and admitting some exceptions, condemnation would have to be written across the record for which the unqualified practitioner was responsible.

Definition of Principles

The attitude of the medical profession towards unqualified practice (Dr. Hawthorne continued) must be based upon well established and well recognized principles. These principles would emerge if care was taken to note what were the things in relation to unqualified practice which the profession would not and could not do, having in mind the interests alike of medicine and of the public. The first of these negatives was that the profession could not allow it to be a safe and wise course for any person to submit to treatment based upon a diagnosis professed by one who had not undergone the discipline of the medical curriculum and had not justified himself by success in professional examinations. The art of diagnosis, as every experienced medical practitioner would agree, was one of the most difficult enterprises to which the mind of man could apply itself, and if it was true that a stated course of preparation was needed for the practice of architecture or law, or even for the laying of bricks or the shoeing of horses, a fortiori such a course of training was necessary for the art of diagnosis. It was contrary to common sense to suggest that a man was born a diagnostician, or that this gift came to him through hereditary influences, or that it could be acquired by empirical experiences. The claim of the profession was that for the practice of diagnosis the compulsory medical curriculum was essential. Every citizen must be free to select advice from any quarter, but the medical profession could not lend its countenance to the idea that it was wise or prudent for the sick individual to undergo a line of treatment based on the diagnosis of someone who was untutored in the medical curriculum and undisciplined by clinical experience. The second negative followed from the first—namely, that as medical practitioners they could not, and would not, meet in consultation for the purpose of diagnosis any person who had neither the training nor the knowledge to make such consultation useful and fruitful. The third position which must be maintained was a refusal to recognize as a phylar-

thropist or a benefactor a person who possessed on his own showing a remedy for disease, and yet kept this secret and used it for his own personal gain. Such a proceeding might be a piece of smart commercial enterprise, but it was not one which could be recognized by the medical profession either as beneficial to humanity generally or as creditable to the person responsible for it ("Hear, hear"). And yet again, qualified practitioners would not use or administer to their patients substances the nature and composition of which were not openly declared. It was impossible for them, in view of the responsibility placed upon them by the choice of the patient, to indulge in experiment of this kind. As a further negative, the profession would oppose a proposal to allow any group of unqualified practitioners to acquire by Government action a status and recognition which would be readily mistaken by the public as a guarantee of efficient training and competence in the diagnosis and treatment of disease. It was out of these negatives (Dr. Hawthorne concluded) that the attitude of the medical profession could be defined. It might be admitted that in this controversy medical men were to some extent interested parties and therefore could not claim to be quite impartial judges, they would not ask for any legal right to have a monopoly in the relief of suffering and they might further add that if suffering was relieved and people were cured, whether by the qualified or the unqualified, such results were grounds for gratification. They tried to keep an open mind towards knowledge, whether it came from within or without the professional enclosure. And if they held to these positive and negative definitions and acted upon them, they could go steadily and quietly upon their well ordered way, neither seeking controversy nor shunning it, cultivating industriously their own "garden" in the full belief that it was only on the basis of scientific knowledge and carefully garnered clinical experience that the safe and successful practice of medicine could securely rest. (Loud applause)

The Need for a Broad Outlook

SIR WILLIAM WILCOX said that all those present would agree that no one should practise as a doctor—namely, undertake the responsibility of diagnosing a case, of dealing with the complications which might arise, and of laying down the main principles of treatment—unless he had had a proper training, or, in other words, held a medical qualification. That was where the danger lay if certain unqualified persons, such as osteopaths, were allowed to make diagnoses and prognoses and to undertake the management of treatment. He did not quite understand, however, what was meant by "unqualified practice" in the title of the discussion. There were certain aspects of treatment which after the diagnosis of the case had been made and the general lines of treatment decided by a qualified practitioner, might be undertaken by persons who had not medical qualifications. The governing factor in all these matters was the public interest. It was futile to argue in a court of justice or before any lay assembly that a certain procedure should be adopted because it was in the interests of the medical profession. On many occasions he had given evidence in cases where unqualified practice had been concerned, and when the counsel had said to him, "You don't approve of this because it is not in the interests of the profession?" he had answered "Rubbish! I do not care about the interests of the profession in this matter, this is not in the interests of the public." Everyone present could quote instances of tragedies which had occurred as a result of unqualified persons undertaking the treatment of cases. He had seen cases of sarcoma of the femur and of tuberculosis treated by unqualified practitioners with dire results. He recalled a case, a few months ago, of a girl dying of renal disease, her abdomen full of fluid, and the osteopath who was called in, having no knowledge or training, declared that this accumulation of fluid was due to defective action of the liver and treated her accordingly, she died within a few days. It was interesting that, as Sir Holburt Waring had indicated, the medical profession was not protected as the dentists were, nevertheless, it got its protection indirectly, and the privileges of medical men were very great. It was necessary for them, however, to cultivate a

broad outlook Pasteur, one of the greatest of physicians, was not a qualified medical man. The late Sir William Bragg, the distinguished physiologist, had no medical qualification, and the same was true of other great teachers in medicine. Any line of treatment which appeared to be of value to the public should be sifted carefully and without prejudice. In connexion with electricity, "artificial sunlight," surgical instruments, and in other directions much valuable work was being done by people who were not qualified, but there would be general agreement with Dr Hawthorne that in respect to the diagnosis, prognosis, and the general management of a case the responsibility should be undertaken only by those who had been through the proper training.

Advantages to the Public of Registration

Mr McADAM ECCLES remarked that a few years ago the largest theatre in one of the medical colleges of London was packed to the doors to hear a man whose name was known the world over deliver an address "On the advantages of being unregistered." His name was George Bernard Shaw. He made out his case with such effect that some of those who listened to him felt that if they had their time over again they would never become qualified and registered practitioners. But this question, whatever its aspects from the individual angle, was fraught with enormous public importance. Was it or was it not advisable for intending members of the medical profession to pass through a fairly long course of training—not less than five years, and in his experience averaging six—and then to satisfy examiners before being granted a qualifying degree or diploma entitling them, not to treat all the ills that flesh was heir to, but to be registered by the General Medical Council? Registration was not altogether, in one sense, an advantage to the practitioner, as Mr Shaw had shown, but there would be general agreement that it was to the advantage of the public. What, then, should be the attitude of the profession to the unqualified and unregistered? There was only one answer. Believing that it was for the good of the public that there should be qualification and registration, they should stand aloof in every way from the unqualified practitioner. By the unqualified practitioner he meant the man who was out on his own, of course, nurses in a sense treated patients, and were medically unqualified, and the same was true of masseurs and others, but these were not out on their own—they were respectable in their various professions and callings because what they did they did under the control of the qualified and registered practitioner. That was just the difference between the unqualified quack and the persons who, while legally unqualified, were quite capable of carrying out treatment under proper direction. Between the medical profession as a whole and those who were unqualified and unregistered there were certain differences which ought to be fixed quite fearlessly. The first was that the volume of work done for no fee or reward by qualified and registered practitioners of medicine and surgery was far, very far, greater than that which was done by the unqualified and unregistered. (Applause.) The second was that the amount of advertising, direct and indirect, by unqualified and unregistered practitioners was very far greater than any type of advertising—always to be deplored—in the ranks of the qualified and registered profession. (Applause.) Mr Eccles added that before very long a strong effort would be made to secure registration for a certain type of unqualified practitioner. At the present moment, in a London directory, there were thirty of these practitioners—many of them practising in Park Lane—and the efforts, direct and indirect, to secure registration on their behalf would be very great. The medical profession must oppose that sort of registration through thick and thin. Every type of treatment which was good was available through the medical profession, and, where necessary, could be obtained by the public without fee through the medical profession in the recognized hospitals. (Applause.)

Dr T. P. BEDDOES thought there was something to be said for persons, qualified or unqualified, who devoted their attention to one subject—a subject to which in some cases hereditary traditions inclined them—and became experts. Sometimes great things along this line had developed from

what was originally unqualified practice. He gave several historic instances, one of them from bone-setting. With regard to ophthalmology, Dr Beddoes said that there were some junior ophthalmic surgeons who were in favour of prescribing by opticians, because large numbers of the public could not afford the fees of the medical expert to fit their eyes.

Position of Osteopaths and Chiropractors

Dr E. GORDON FLEMING, who was called upon by the CHAIRMAN as being one of the qualified medical practitioners who were in sympathy with osteopathy, said that he spoke rather as a chiropractor than as an osteopath. The remarks made by Sir Holburt Waing in his recent address to the Medical Society of London (BRITISH MEDICAL JOURNAL, October 17th, p. 679) with regard to the training of chiropractors were true: they were untrained except with regard to certain manipulations, but, on the other hand, the work they did was extremely beneficial. The patient who usually came to the chiropractor was a person with some chronic complaint who had already been treated by other medical men without satisfaction to himself. People rarely came to the osteopath or chiropractor of their own accord before seeing other medical men. He did not agree with Mr McAdam Eccles that every type of treatment that was good could be obtained through the medical profession. Osteopathy and chiropractic were not available to poor people, for the reason that there were very few practitioners in these arts—only four registered men in Great Britain—and there was not the opportunity for continuous clinical observation. Dr Hawthorne had said that the triumphs of the unqualified practitioner were blazoned abroad and his failures were written in water. No doubt, if a patient received benefit from an unqualified man, after failing to do so from a qualified, the patient was inclined to act as an advertising agent, but, on the other hand, the failures of the practitioners of these cults were brought strongly to the notice of the medical profession, and they were stigmatized more than they deserved. He was not pleading that these people should have any separate registration, because he thought they should first take the trouble to go through the ordinary curriculum, but he did plead for prolonged clinical, and if possible experimental, investigation of their methods.

Mr PHILIP FRANKLIN believed that the medical profession would have to be protected in the same way as the dental profession was already protected, and anyone not on the Medical Register should not be allowed to practise. Osteopathy was increasing in this country, some fifty persons held a degree of "doctor" in this subject, and he thought that these men, if they wished to practise, should go through the medical curriculum which was necessary for entrance into the qualified medical profession of Britain.

Sight-testing Opticians

Mr BISHOP HARMAN said that the passing of the Dentists Act, 1921, was a good illustration of Dr Hawthorne's contention with regard to the interests of the public. Why was it necessary for the State to impose a Dentists Act restricting dental practice to persons on a *Dentists Register*? It was because unqualified practice had been killing qualified practice, and if the State had not stepped in there would have been no proper position for dental treatment in this country. The public did not know whether a dentist under the old system was qualified or not, they were attracted by his advertisements on his house front or in the newspapers. Dr Beddoes had stated that young practitioners were content to have their patients go to sight-testing opticians because the patients could not afford relatively large fees for expert advice in the provision of such necessary equipment as spectacles. [Dr Beddoes's remarks referred to junior ophthalmic surgeons.] But recently the British Medical Association had compiled a list of between 600 and 700 qualified medical men who were able and willing to treat insured persons in connexion with ophthalmic benefit. Owing to ignorance which was not quite excusable, some practitioners continued to send their patients to the advertising optician. Ophthalmic benefit for insured persons would shortly be one of the regular benefits under the Insurance Acts, and a great contest for the provision of that benefit was inevitable. Certain opticians were striving their utmost

to get a supplementary register of opticians, though opticians were so divided amongst themselves that their success in anything which required a united effort was not very likely. But the result of such a supplementary list would be to push out the really trained men. It was difficult to conceive that people should be willing to hand over the most precious, sensitive, delicate, and complicated of all the sense organs to the unqualified person who had been taught by a private company banding themselves together for that purpose and giving him what looked like distinguished letters following his name. The speaker hoped that full regard would be paid to the public interests in this matter.

Lord Dawson's Summing-up

The CHAIRMAN (Lord Dawson of Penn), in summing up the discussion, posed the question why the public supported unqualified practice. In his view it was due to the persistence of a belief in the miraculous which had come down from the Middle Ages. Perhaps the medical profession would do well first of all to exorcise any similar belief from its own body. Was there not often a subconscious feeling that there might be, after all, a short cut to salvation other than the road of scientific endeavour? It was a belief in the miraculous which made people an easy prey to plausible talk. With regard to osteopathy, he was free to admit that he had known an osteopath to do much good. The osteopath was often an expert manipulator, and in addition he was gifted with the power of suggestion. The human mind, so curiously constituted, looked for some physical explanation, as definite and localized as possible, of any illness, and when the osteopath, regardless of facts, referred all ills to the spine he supplied "a physical hook on which to hang the coat." If the public were told that it was suggestion they would accuse the profession of a narrow and prejudiced view, but that, nevertheless, was in very many cases the basic fact. He agreed with Dr Hawthorne that there must be not the smallest concession to unqualified practice on any question relating to diagnosis. The question of treatment raised certain other considerations. It had to be remembered that medicine was widening its bounds, calling to its aid certain ancillary sciences, and venturing into various realms, such, for example, as chemistry and physics. All this might necessitate a review of the position with regard to the organization of treatment. In some branches it might be necessary to employ technicians, strictly under medical supervision, who were not themselves medical men. He had found this practice in being during his recent visit to Canada and the United States. Highly educated people—college girls, for instance—were employed as technicians in laboratories. In Toronto there was even a degree of "Bachelor of Science Medical," attainable by persons in various departments who were highly trained in some subject ancillary to medicine. These persons had no right to practise, but they could study a certain amount of medicine in the wards. In this country medical men did too much detail work, they carried at one and the same time as subalterns and colonels. Here, therefore, was one constructive line on which possibly to meet this big question of unqualified practice. The general control of all the means of treatment must be maintained by the medical profession, but a certain amount of work might be delegated. When diagnosis was in question, however, there could be no possible delegation.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER

THE Royal Commission on Lunacy held sittings on December 10th and 11th, under the chairmanship of Mr H P MACMILLAN, K C, to hear further evidence from the Board of Control and from the Ministry of Health, and it was understood, although no public announcement was made, that this concluded the evidence which the Commission proposes to take.

The Board of Control's Scheme

SIR FREDERICK WILLIS (Chairman of the Board of Control), who was accompanied by Mr Fraser Macleod, K C, and Dr C H

Bond (Commissioners), gave evidence in answer to a questionnaire which had been submitted by the Commission to the Board. He stated that for the purpose of settling the procedure to be adopted for the treatment of persons suffering from mental illness it was desirable that patients should be divided into three classes: (1) voluntary, (2) non-volitional but passive, (3) resistant. A voluntary patient, he thought, should be received for treatment, on his own application, accompanied by one medical recommendation, in any mental hospital, registered hospital, licensed house, general hospital, nursing home, or private care, subject to certain conditions. The conditions were that notification of the admission of the case, with a copy of the medical recommendation, should be sent to the Board of Control, that a medical report should be sent to the Board within seven days of admission, and thereafter at intervals of six months, each such report to contain the statement that the patient was in need of further treatment and was willing to remain, that the Board should have the right of inspection of the institution, that it should have the right to order the discharge of the patient from the voluntary class should it consider him unsuitable to remain on that footing, that if the patient ceased to possess real volition, and this condition continued, he should within a month be dealt with under the provisions relating to passive or to resistant cases, or should be discharged, and that the patient should have the right to leave the institution at any time on giving seventy-two hours' notice in writing. Sir Frederick Willis explained that twenty-four hours' notice did not give sufficient time for communication with the friends of a patient when this was necessary in a case which needed a longer stay.

The Chairman thought that instead of the Board having the "right" of inspection of approved institutions it should have the duty of inspection, and Sir Frederick Willis agreed.

With regard to the non-volitional but passive case, Sir Frederick Willis said that his Board was in favour of a patient of this class being received for treatment in any mental hospital or registered hospital, or—if the place had previously been approved by the Board—in any licensed house, general hospital, nursing home, or private care, subject again to certain conditions. These conditions were that an application should be made by a relative or friend or public official for the reception of the case, accompanied by two medical recommendations, that the admission was immediately notified to the Board, that copies of the recommendations, that a medical report was sent to the Board within seven days of the admission, that the institution was open to the inspection of the Board, that the Board had the right to order the discharge of the patient from the "passive" class if he was considered unsuitable, that if a person on whose application the patient was received for treatment should at any time have the right to remove the case on giving twenty-four hours' notice, that if the patient recovered volition he should be allowed to leave on giving seventy-two hours' notice, and that if at any time the case became a resistant case it should within one month be dealt with under the provisions relating to that class or should be discharged.

Lord Russell objected to the condition that the person on whose application the patient was received for treatment should have the right at any time to remove the case. This seemed to make the petitioner the sole custodian of the lunatic.

Sir Frederick Willis, however, pointed out that in the cases it was undesirable to have any element of detention beyond that involved in the three days' notice. He also thought that the non-volitional but passive patient should only be received on that footing for a period of six months in the first instance, but that there should be power to extend the period for a further six months if the independent medical practitioners so recommended. If after having been treated under such conditions for a year it was considered that the patient should be detained for further care and treatment, this should only be done on full certification. If after full certification he recovered volition and was willing to remain as a voluntary patient he should be allowed to do so, subject to the conditions relating to voluntary patients. With regard to the resistant case, this should be detained after full certification on a petition signed by a relative, friend, or public official, and an order signed by a judicial authority. A case might, however, be received on a provisional order, accompanied by one medical certificate. Such a patient might be detained for fourteen days if in the opinion of the medical officer of the institution (or, in single care of the medical attendant) he needed detention, and this period of fourteen days might be renewed for a second similar period, but beyond twenty-eight days the detention of the resistant case should only be allowed under the order of the judicial authority on petition. These cases during the provisional stage should only be received where suitable accommodation and expert medical treatment and nursing were available. They might go to any public mental hospital, registered hospital, or licensed house, and, if the institution or place had previously been approved by the Board for the reception of cases under a

provisional order and certificate, in any general hospital, nursing home, or single care, or in a Poor Law institution. Provisions for dealing with urgent cases, similar to those of Section 20 of the Lunacy Act, 1890, must be retained. During the three days steps must be taken to obtain a provisional order. Cases fully certified should be received only in public mental hospitals, registered hospitals, and licensed houses, or in single care, but they might also be received in Poor Law institutions or in nursing homes which had previously been approved by the Board of Control.

Sir Frederick Willis considered that the public responsibility for providing for all mental cases should rest with the visiting committee of the local authority, and not with the guardians of the poor, and if any Poor Law accommodation was used it should be used in pursuance of a contract between the visiting committee and the guardians.

The Ministry of Health

The Commission met on December 11th expecting to take the evidence of Mr L G Brock, Principal Assistant Secretary of the Ministry of Health, but Mr Brock was prevented by illness from attending, and in his place Mr H W S Francis, an assistant secretary of the Ministry, offered some observations.

The Chairman said that it was generally appreciated that there was an intimate relationship between the existing code of lunacy administration and the Poor Law. The Commission, in the course of its investigations, had been considering the general question of that relationship, and he hoped the Ministry would assist it by any observations on the possibility of extricating lunacy administration from Poor Law administration. At present there was an unfortunate element of pauperization associated with lunacy, and the Commission desired to know how that could be removed.

Mr Francis said that patients who were accommodated in institutions provided by the guardians were on that account regarded as paupers. Some mental patients became paupers, from economic causes, before the onset of their malady, but there were others who had had no relation with the Poor Law until their malady began. The lunatic population in Poor Law institutions might, in fact, be divided into three classes: (1) patients who went into the workhouse as a receiving house on their way to the asylum (unless in the meantime it was found that asylum treatment was not suitable or necessary), (2) persons already paupers who became insane while in the workhouse, (3) persons discharged from asylums and going back to the workhouse, where they were detained under other provisions of the Act. If it was held desirable to take over parts of Poor Law institutions by the county or municipal authority for the purpose of housing mental cases, this could be done under Section 26 of the Lunacy Act, 1890. Even though lunacy administration were taken out of the Poor Law, it would almost certainly still be necessary to use Poor Law premises for mental patients to some extent. A certain part of a Poor Law institution might be set aside for this purpose and be regarded as under the control of the local authorities other than the Poor Law authorities. A parallel was afforded by the use of Poor Law institutions at present for the reception of maternity cases sent there by the health authority. No part of the expenditure for these mental cases should fall ultimately upon the guardians, for although the expenditure in the first instance would be met by them they would be entirely indemnified. Both the Poor Law premises and the infirmary staff might be used so long as the whole cost was met from some source other than the Poor Law funds. The local authority could lease the premises from the guardians and recoup the guardians for the cost of maintenance. The Board of Control would inspect the premises, and would make any representations, not to the guardians, but to the Poor Law authority for the area. The lunacy authority would then be responsible for all cases arising in its area, irrespective of the Poor Law. The relieving officer as such would have no function so far as lunacy was concerned. The procedure would be for the doctor who was called in in the first instance, if he thought the case required institutional observation or treatment, to communicate with the medical officer of health, who would then put the appropriate machinery in motion for the admission of the patient into a receiving home. In his view the medical officer of health and his staff offered the most suitable alternative to the present procedure for dealing with the present Poor Law cases, and in this way the pauperization stigma would disappear. He saw no difficulty in the case of persons already in receipt of Poor Law relief who became mentally afflicted, these people were initially paupers, on developing mental illness they would pass under a different administration, and on recovery would simply return to the pauper status. Asked whether the accommodation and facilities at present provided by the guardians were "a fair standard," Mr Francis said that generally he thought they reached a fair standard. In some instances they were good, in others not so good.

England and Wales.

VITAL STATISTICS FOR 1924

The Registrar-General's statistical review of England and Wales for 1924, Part II (Civil), has been issued, and can be obtained from the Stationery Office, price 5s net. The estimated population of England and Wales on June 30th is given as 38,746,000, as against 38,403,000 in the previous year. On December 5th (p 1089) we referred to various statistics which appear in Part I of the statistical review, but it may be added that the marriages during the year show an increase of 4,008 over the previous year. A special table shows the mode of solemnization of marriages in 1924, and it is strange in these days of compulsory education to note that 954 men and 1,051 women signed the marriage register by mark. The number of decrees nisi made absolute during the year was 2,286, as compared with 2,667 in 1923, and 2,588 in 1922. The number of parliamentary electors on the autumn register was 18,806,842, an increase over 1923 of 221,743 men and 186,266 women.

COST OF MATERNITY AND CHILD WELFARE SERVICES

The Ministry of Health has asked local authorities to supply a forecast of expenditure during 1926-27 on maternity and child welfare services. The forecast of expenditure by the London County Council is £11,760, and of receipts £1,200, making a net expenditure of £10,560. This sum includes £4,300 in respect of fees to medical practitioners called in to the assistance of midwives, and £2580 in respect of grants to schools for mothers. The estimate for London is slightly above the revised estimate for the current financial year.

BRISTOL ROYAL INFIRMARY

A new nurses' home, named after the late Henry Herbert Wills, formerly president of the Bristol Royal Infirmary, was opened on December 9th by his widow, Dame Mary Monier Wills, the Duchess of Beaufort presided over the ceremony. The new wing, which cost £25,000, is situated on solid rock, and during the excavations several springs were discovered, so that the supply of water is assured. All the furniture in it, with the exception of the chairs, has been made in the workshops of the infirmary. The building is an essential part of the expansion of the infirmary, where the waiting list is very long. The original estimates have been exceeded by 25 per cent, and the time taken in building was two years.

PENSIONS FOR HOSPITAL OFFICERS AND NURSES

A draft scheme of pensions for hospital officers and nurses has been prepared by a conference composed of representatives of King Edward's Hospital Fund for London, the British Hospitals Association, the Incorporated Association of Hospital Officers, and the College of Nursing, Ltd., under the presidency of Lord Stuart of Wortley. The conference was convened by King Edward's Hospital Fund at the request of the other three bodies, and traces its origin to a special committee of inquiry appointed by the King's Fund in 1914, the report of which was issued in 1919. The memorandum contains a very careful and detailed examination of the existing systems of pensions, the various problems involved, and the general principles of the combined scheme suggested. The hospitals adopting such a scheme might contribute 10 per cent of salary and emoluments, and the officers and nurses 5 per cent, towards the fund. The normal pension age would be 60 for officers and 55 for nurses, and three main types of policy would be provided: an endowment assurance with a fixed rate of annuity at the retiring age, or a definite sum if death occurred previously; deferred annuities, with return of the premium at premature withdrawal or death; and deferred annuities without return of premiums. Such a scheme would include the salaried staff—administrative, clerical, and dispensing—and also the whole nursing staff except probationers during their first year. Members

* Obtainable from Messrs George Barber 23 Farnival Street Holborn, E.C.4, price 1s post free.

moving from one hospital to another, or from one branch of a nursing service to a different one, would not forfeit their benefits, thus, a junior officer would be able to apply for a higher post elsewhere without endangering his pension rights, or the new hospital being obliged to undertake increased liabilities. The whole working life of the nurse would be covered by the scheme, which would enable her to make adequate provision for old age, special arrangements are suggested for those engaged in private nursing. The scheme would be administered by a central council representing the hospitals and the members, and this council, through a special nurses' committee, would deal with nurses not in hospital service.

Scotland.

GLASGOW WESTERN INFIRMARY

Two new memorials were unveiled in the chapel of the Glasgow Western Infirmary on December 12th, in the presence of a large number of nurses and members of the general public. The matron of the infirmary, Miss Gregor Smith, unveiled a memorial in memory of Lieutenant Donald Mackintosh, V.C., son of the superintendent of the infirmary, Colonel D. J. Mackintosh, C.B., M.V.O., which took the form of two stained glass windows erected by the Nurses' League. A tablet was unveiled also in memory of two nurses, Sister Ellen Mund Bond and Staff Nurse Margaret S. Derris, who lost their lives in the war. The Rev. George H. Morrison, D.D., conducted a commemoration service, and delivered an address in which he recalled the high esteem and affection in which those whom they were commemorating had been held. Such a joint commemoration was particularly appropriate because of the united comradeship, co-operation, and self-sacrifice of the two sexes in the great war. Colonel Mackintosh for many years had directed the Western Infirmary with a grasp of detail which had placed him high in the ranks of organizers, no man had surpassed him in devotion to the welfare of the great nursing profession. It was, therefore, fitting that in remembering the son the Nurses' League should also bear the father in mind. The two windows were the first of a series to be placed in the chapel. The matron of the infirmary, unveiling the memorials, spoke of the high esteem and regard in which Lieutenant Mackintosh and the two nurses had been held by the infirmary staff. Colonel J. A. Roxburgh, accepting the custody of the memorials on behalf of the infirmary board of managers, said that they would serve to remind them of the spirit of devotion to duty and self-sacrifice which had always distinguished the medical and nursing professions. At the conclusion of the service wreaths were placed at the base of the memorials.

EDINBURGH ROYAL INFIRMARY

At a meeting of managers of the Royal Infirmary of Edinburgh on December 7th the retirement of Sir Norman Walker, M.D., F.R.C.P., from the post of dermatologist to the institution was announced. Reference was made to the fact that he had been associated with the skin department since May, 1892, when he was appointed assistant physician for diseases of the skin, and also to the fact that since October, 1924, he had been engaged in testing the value of artificial sunlight in the treatment of lupus in the Royal Infirmary. The managers invited him to accept the post of consulting dermatologist to the Royal Infirmary. It was reported that the receipts during the previous three weeks had amounted to over £7,010. It was also intimated that the Royal College of Physicians had elected as its representatives on the board of management for the year 1926 Dr. James C. Dunlop and Dr. William Russell, while the university had nominated Professor Harvey Littlejohn and Professor William Wilson.

SCARLET FEVER EPIDEMIC IN EDINBURGH

A considerable outbreak of scarlet fever, affecting especially school children, began in Edinburgh during the last

half of November. For the week ending November 21st there were 102 notifications, and for the week ending November 28th 52, for the week ending December 5th the number of cases reported was 7, which is practically a normal figure.

Ireland.

ULSTER MEDICAL SOCIETY DINNER

The annual dinner of the Ulster Medical Society was held in the Medical Institute, Belfast, on December 10th. Professor R. J. Johnstone, M.D., M.P., occupied the chair in the unavoidable absence of Mr. James A. Craig, F.R.C.S., owing to illness. After dinner the chairman proposed "The King," which was duly honoured. Later he referred to the absence of their president, who, he said, had bidden him convey to the Fellows and guests his apologies and regrets. He (the chairman) was sure that they would allow him to tell Mr. Craig how much they missed him and then hopes that he would soon be among them again, of which there was every prospect. The following toasts were given: "His Grace the Governor and Prosperity to Northern Ireland," by the chairman, and responded to by the Marquess of Dufferin and Ava, "The Legal Profession," by Mr. Howard Stevenson, and responded to by Lord Chief Justice Moore, "The Guests," by Professor Lindsay, and responded to by Vice-Chancellor Livingston, and by Dr. T. Henry Wilson, Dublin, President of the Royal College of Physicians, "The President," by Dr. Colville, and responded to by the chairman, who said that he would convey to Mr. Craig all their good wishes, he asked them to respond to the toast of "The Honorary Secretary," who had done all the hard work, and Dr. Berth, in replying, warmly associated Dr. Marshall, ex-secretary, with himself, as the latter had given him most willingly all the benefit of his experience. During the evening Dr. Morrow and Mr. Christy gave some recitations and songs, which were much appreciated.

PROPOSED UNIFICATION OF APPROVED SOCIETIES (IRISH FREE STATE)

The Association of Trade Union Approved Societies in Ireland at its first annual meeting passed the following resolution:

That this conference views with alarm the recommendations of the Committee of Inquiry into Health Insurance and Medical Services that all insured persons should be automatically transferred to a unified society, in the management of which they would have no voice and which would be at the same time outside the control of the Oireachtas. We insist further that unless the health insurance scheme is administered directly as a State service, any attempt to prevent freedom of choice in the selection of an approved society is an unwarranted interference with the rights of insured persons.

WESTMORLAND LOCK HOSPITAL, DUBLIN

During the year ended March 31st, 1925, the Westmorland Lock Hospital, which was founded in 1755, reports a slight decrease in the number of patients treated, though it is admitted that this cannot be taken as evidence of diminution in the incidence of venereal disease in Dublin. The relative numbers of married women, single women, and children remain very constant year by year. The routine treatment employed for syphilis is novarsenobillon, but for patients who cannot tolerate arsenic, or after prolonged arsenical treatment return a strongly positive Wassermann reaction, such bismuth preparations as the oxychloride and suspensions of metallic bismuth in glucose solutions have been used. Alternating courses of novarsenobillon and bismuth were found beneficial in cases of a persistently positive Wassermann reaction. Bismuth seemed to be the more effective remedy in the treatment of syphilis of the central nervous system and of syphilis in young children.

EPSOM COLLEGE

ROYAL MEDICAL FOUNDATION

SIR,—Last Christmas I humbly approached your readers on a note of entreaty this Christmas I approach them on a note of gratitude, not unmixed with a hope of further favours to come. We have won the support of many additional annual subscribers, but, like Oliver, I am still handing up my plate for more. A most gratifying response has come from the Panel Committees throughout the country, without any question of *quid pro quo* they have just done what they could, and certainly one who owed his success in the election last June to their activities. We are deeply indebted also to our many honorary local secretaries, some of whom have sent us most substantial returns, and to the great medical institutions, the British Medical Association and its *Journal*, the *Lancet*, and the Medical Insurance Agency. So strenuously did the Pathological Society, under the leadership of Professors Dearn and Boycott, canvass new subscribers that it secured at the first attempt a high place on the list of successful candidates for the son of a recently deceased pathologist. The increased subscription list has enabled us to do many things a little better, and to give materially greater advantages to our fifty Foundation Scholars. In the school department substantial improvements in the salaries of some of our masters have been made—a very important step, for good teaching is a basic requirement.

In the matter of legacies and benefactions we have been very fortunate too. It is on these that we depend almost entirely for the immediate provision of the more costly improvements that we effect. The rebuilt chapel—a war memorial mainly provided by Old Ipsomians—was dedicated last February, a well known Old Ipsomian has beautified it with a gift of handsome silver-plated candlesticks, vases, and an alms dish, and has also been instrumental in securing a contribution of £1,000, which by his wish is being spent on Gothic oak panelling for the chapel. Four generous donors contributed a total sum of £1,300, which has permitted a complete transformation of the library and a good equipment of new books. We have promises of the bequest of parts of two valuable libraries, but let me hasten to say that we welcome suitable books from the living as well as from the dead. If each medical man were to give one well bound book, what a library we should have!

Carefully husbanded legacies have enabled us to lay the foundation stone of a new chemistry block by the hand of our President, Lord Rosebery, and we intend to open it next midsummer on Founder's Day. This is costing rather more than £10,000. At the same time we are taking in hand the concentration at a cost of some and nearly worn-out heating installation for washing and drying £5,000, and we can see our way also to much-needed additions to the accommodation for washing and drying for the boys in the lower school—another £2,000 or more. There we reach the bottom of our pocket, until kind friends of the College can give or influence the giving of legacies or benefactions for other objects of which I venture to name a few.

The provision of a new infirmary would be a priceless boon to the school. The present infirmary is not constructed according to the requirements of modern medicine and nursing, and is uneconomical to run. Our medical officer has plans for a model school infirmary, which would cost from £15,000 to £20,000. The invited infirmary would give accommodation to forty-five more boys from our waiting list, which now totals nearly 500, and this addition to the total numbers would make the school a much more economical unit in many directions. What a chance for a wealthy patient as a thank offering for life or limb, and for the council to inscribe his name on it in perpetuity!

More houses for married masters are a standing need, as also is an entrance lodge adjoining the college quadrangle. Some sportsman may be tempted to build a

sports pavilion or to undertake the much needed levelling of the lower school playing fields.

But in drafting these grandiose proposals before the eyes of potential benefactors, we must not lose sight of our humble daily needs, whereby we educate and maintain our Foundation Scholars free of cost, and distribute also many pensions, if funds were available we should like to increase these pensions, owing to the present high cost of living.

One guinea annually, or a single donation of ten guineas, makes a governor and gives ten votes at each election in June of foundationers and pensioners, and each additional guinea gives ten votes more. We already relieve much distress in the profession will you help us to relieve much more?

Subscriptions and donations may be sent to the Secretary, Epsom College Office, 49, Bedford Square, London, W.C.1, who will be glad to give any information and welcomes personal visits at any time—I am, etc.,

RAYMOND CRAWFORD,
Chairman of the Council of Epsom College.

London Dec 3rd

EDUCATION OF THE PUBLIC AS TO CANCER

SIR,—The late Walter Hines Page, American Ambassador in London during the war, was characteristically outspoken in his judgement of the British nation. Though he admired without stint many of their qualities, he confessed that as a people they were too slow for words. It may be admitted that "slow but sure" is an admirable trait, but "slow when sure" is not so manifest a virtue. Now it has been abundantly proved during the present generation that cancer *per se* is not an incurable disease—that is, that if it occurs in an accessible region and is removed early enough it may never return. And acquaintance with all records, during the present century, during the conviction that these records could have been vastly improved were it not that so many patients applied too late for anything hopeful, from the point of view of cure, to be done for them. Yet the obvious and only remedy for this—that is, supplying the potential victims of cancer with the knowledge which would enable them to apply in time—remains pigeon holed as far as the medical profession generally is concerned, whereby annually thousands of lives that could indubitably be saved are inevitably lost.

Here and there is heard a voice crying in the wilderness—to wit, Winter's effort in regard to cancer of the uterus, my book *The Control of a Scourge, or how Cancer is Curable*, published in 1906, six years before the American Society for the Control of Cancer was founded, an attempt three years ago to induce the Royal Society of Medicine to move in the matter, the half-hearted circular to local authorities emanating from the Ministry of Health in 1923, Wright's book and my own *Cancer and the Public*, published this year, lastly, letters and papers in various medical journals, such as Young's in your last issue. Yet nothing emerges. Medical opinion generally hesitates to give its imprimatur to the initial effort. The one and only objection that can be urged is the production of panic, yet the experience of the American Society for the Control of Cancer, which has been in operation a dozen years, and which employs very sensational (in my opinion far too sensationally) measures to disseminate knowledge about cancer, is that there is no evidence whatever of any increase of cancerophobia in America owing to its educational campaign, in fact, that its efforts have resulted in nothing but good. Statistics of various surgeons, some of which are quoted in Dr. Young's letter, corroborate this fully, and, as he points out exactly the same boys who trotted out in relation to the antituberculosis crusade, there is no doubt that if a campaign for the education of the public was seriously launched, county and borough councils could quite easily set the necessary machinery in motion and keep it going. The most important precaution would be to secure that where literature and public meetings were concerned in the campaign, the public, and that section alone of the public which had reached the usual cancer age—that is, those of middle life and over—should only be told what might really be of use

to them, and in language which was calculated not to alarm them, in other words, strict discrimination should be exercised in the dissemination of literature and in the selection of speakers. A scheme of a cancer campaign for the education of the public by local authorities is given in detail in my latest book, *Cancer and the Public*—I am, etc.,

CHARLES P. CHILDS, B.A., F.R.C.S.

Portsmouth Dec 14th

SIR,—I am glad to see that the attention of your readers is once again called to this important subject by Dr. James Young in your issue of December 12th (p. 1147). At the Annual Meeting of the British Medical Association at Bradford in 1924 I read a paper on this subject which created much interest, and as the result several cancer committees were formed in various towns. In my own city, largely through my influence on the Public Health Committee, a cancer subcommittee was formed, and as the result of our deliberations a circular was drawn up, specially directed to women, drawing their attention to the question of seeking early medical advice on the appearance of early symptoms, and of avoiding running risks. There was some opposition to the circular, but it was agreed to, and was ordered to be distributed throughout the city, one copy at every house. This was supposed to have been done. As a result of this circular the medical officer, in his report for 1924, says "As a result of this, a good many women have applied for information about doubtful lumps." Surely a little more than this might have been said of an effort that entailed a considerable amount of work, and was the least costly to the ratepayers. I may add that the report gives no credit to the cancer subcommittee, the medical officer of health ignoring its existence.

The report goes to show that during the year there were in Birmingham 159 more deaths from cancer than in any previous year. It then explains that this was due to the fact that in every 1,000 of the population there existed a much larger number of persons at ages most likely to be attacked by cancer. What the increase in the number of persons of the cancer age—namely, above 45—was is not stated, but it is certain that this increase alone does not account for the 159 more deaths from the disease than have occurred in any previous year. The publication and issue of the circular to women was undertaken in the hope that, by the education of the public, the death rate from cancer could be reduced, but the half-hearted way in which the proceeding was carried out defeated the end in view.

On submitting a rough draft of the circular to an eminent medical man the question was asked "What man living ever smokes a clay pipe with a jagged end?"

Within a week of being asked this curious question I happened to mention it to an out-patient surgeon in one of our large hospitals, who informed me that two or three days previously he had seen a man with epithelioma of the lip, who was smoking a broken clay pipe, and had been doing so for many months. Why, then, should objection be taken to my calling attention to a perhaps uncommon habit, but one which every man of the world knew existed?

I have mentioned these points because I entirely agree with the statements made by Dr. James Young, and, while in previous articles I have advocated the formation of local committees for the purpose of dealing with the cancer problem, I am now more than convinced that the only way of dealing properly with the subject is for the Ministry of Health to take the matter in hand, and issue instructions to all public health authorities as to the way in which education on the cancer problem is to be broadcast.

I have no hesitation in saying that the public, armed with the knowledge of the disease at present at the command of the medical profession, could reduce, by their own efforts, the death rate from cancer by 25 per cent within a couple of years.

A sporadic crusade against cancer is useless. Nothing but a continual hammering propaganda campaign is likely to produce the results which I am convinced are within our reach. Objection to such a campaign on the ground of producing alarm and panic are all futile and unproved, and there exists no reason why the spread of knowledge on

the subject of cancer should produce results different from those achieved by the spread of knowledge concerning tuberculosis—I am, etc.,

Birmingham Dec 12th

J. HILL EDWARDS

SIR,—I read Dr. James Young's letter (BRITISH MEDICAL JOURNAL, December 12th, p. 1147) on the education of the public as to cancer with much pleasure, and trust it will meet with the serious consideration it deserves. The number of late or inoperable cases of cancer still met with in hospital, and particularly Poor Law hospital, practice is much too great, and is due, in large measure, to the popular belief, for which our profession is largely responsible, that cancer is incurable. Persons afflicted with tumours, who hold this belief, naturally postpone the evil day when they must go to a doctor and have their doom confirmed, and thus allow the period in which a curative operation might be performed to pass.

I have for many years taught that many cases of carcinoma are curable by operation, and in my textbook on surgery say "If all medical men, and through them the public generally, could be taught to regard surgical interference, not as a last resource, but as the proper treatment of carcinoma as soon as detected, the results would undoubtedly be still better." I have also urged the students to do all in their power to educate the public as to the hopefulness of early operation, and thus encourage them to see a doctor as soon as they noticed any suspicious swelling.

But I agree with Dr. Young that further steps are necessary to educate the public, and trust that his letter will lead to prompt and energetic action being taken—I am, etc.,

Glasgow, Dec 14th

JOHN A. C. MACFARLANE

THE LEAD TREATMENT OF CANCER

SIR,—The following is the actual text of the correspondence, except for the omission of a name, that passed between Mr. Joll and myself, together with the last letter sent to one of my colleagues on the Cancer Research staff, before the matter was brought to my notice.

"October 6th 1924

"Dear Mr. —, "Many thanks for your kind letter. I suppose it would not be possible to get an account of how preparation S3 is manufactured? Perhaps that is a secret they would not care to reveal, but I have no doubt I could get it made up if the details were forthcoming.

Again many thanks

"Yours sincerely,
(Signed) CECIL A. JOLL."

"October 17th 1924

"Dear Mr. Joll, "— has consulted me about your correspondence with him. We are continually receiving requests from all over the world exactly similar to yours. We have however so far felt that our preparation has by no means reached the level of perfection to which we may be able to bring it. We have not made any attempt to ensure secrecy as you suggest. I can only presume you have not read my publications.

"At the present moment the committee and I are engaged in endeavouring to reorganize our arrangements, and until this is done I can enter into no discussion as to what may be possible in the future. There is no one more anxious than we are that suitable cases should be treated all over the world. I can however go so far as to say that it is unlikely that we shall help anyone who is unwilling to come to Liverpool to learn the methods, dangers, etc., at first hand.

"Yours sincerely,
(Signed) W. BLAIR BELL."

"October 20th, 1924

"Dear Dr. Blair Bell, "I think you have misunderstood my letter if you think that I suggested any desire on your part to keep these matters secret. I merely thought that while these matters are experimental you probably do not wish to broadcast the information, which is, of course, in accordance with what is legitimate. I should however, like to see what work is being done on these lines and if you could tell me a convenient day, or days during the early part of November I shall make a point of coming up for that purpose.

"Yours sincerely,
(Signed) CECIL A. JOLL."

"October 22nd, 1924

"Dear Mr. Joll "Thank you for your letter. I am afraid I can no longer undertake to show individuals round except in special circumstances. It wastes too much time as our organization is scattered

I gave a demonstration to the Association of Surgeons and until we have definitely decided on how best the question of teaching outsiders can be tackled I can do nothing.

I think I told you in my last letter that I am busy reorganizing our arrangements, and I am taking into consideration all these matters.

"Yours sincerely,
(Signed) W. BLAIR BELL."

From these letters unprejudiced readers will be able to form their own conclusions as to how far Mr. Jell has truly represented what passed between us, or has misrepresented the whole affair.—I am, etc.,

Liverpool Dec 14th

W. BLAIR BELL

BLOOD TRANSFUSION IN CARBON MONOXIDE POISONING

SIR,—I am very grateful to Professor Haldane for his letter in your issue of December 12th (p. 1146), which throws considerable light on the cases I reported under the heading of carbon monoxide poisoning. I always suspected, and in my report hinted at, another factor, and I now have little doubt that these cases should be labelled methæmoglobin poisoning.

Professor Haldane states that the severe symptoms resulting from carbon monoxide poisoning are not due to existing shortage of oxygen, but to the after effects of shortage of oxygen, and that neither transfusion nor administration of oxygen can be expected to have any good effect in such cases.

Assuming that the severity of the after effects is in direct proportion to the duration of time for which the carbon monoxide remains in the blood, might not both be reduced by early venesection and blood transfusion when possible, or does Professor Haldane consider that this can be accomplished equally well, or better, by the administration of oxygen with 5 per cent of carbon dioxide? Information on this point seems to be of great importance in view of the fact that we read from time to time of fatal cases occurring to motorists working in a closed garage with the engine running.

Assuming adequate facilities, what is the correct procedure for a medical man when faced with a patient found unconscious in similar circumstances?—I am, etc.,

London W, Dec 11th

C. GORDON-WATSON

SIR,—I read the article by Sir Charles Gordon-Watson (BRITISH MEDICAL JOURNAL, December 5th, p. 1049) with much interest. During the past four years I have examined over one hundred cases of death from carbon monoxide poisoning, and have also tested the blood from several cases which have survived. In every instance the blood has been of a pink colour, except when seen in bulk, as, for example, in the large veins. Carbon monoxide blood picked up in the laboratory invariably has the pink colour which is characteristic of this compound of hæmoglobin.

As the very interesting paper by Banham, Haldane, and Savage in the BRITISH MEDICAL JOURNAL of August 1st indicates, this pink colour may occur *post mortem* in cases of poisoning by nitrates, being due to nitric oxide hæmoglobin. In the living body, however, whilst small traces of NO hæmoglobin may be formed, the process does not get beyond the stage of methæmoglobin, which is the first step in the conversion of oxyhæmoglobin into NO hæmoglobin. Nitrites poison by depriving the blood of its oxygen-carrying power just as CO does, but gives a cyanosed appearance as contrasted with the pink of CO poisoning, the cyanosis being due to the presence of methæmoglobin.

The appearance of the blood in cases of methæmoglobinæmia, which is one of the forms of enterogenous cyanosis, is identical with that described by Sir C. Gordon-Watson in his article. In these cases, although the patient is very cyanosed, the lips being lead-blue to black in colour, there is frequently no respiratory distress, a point emphasized in his article. Again, methæmoglobin is practically unaffected by oxygen, whilst CO-hæmoglobin responds to its administration. The spectrum of neutral methæmoglobin shows four bands, but these may be so faint that

only the two bands which correspond in position to those of oxyhæmoglobin are seen, this would explain the spectroscopic findings in Sir C. Gordon-Watson's case. In methæmoglobinæmia the urine is sometimes coloured with methæmoglobin, which gives it a dark colour, this is not met with in the usual form of enterogenous cyanosis, but only occurs when hæmoglobin takes place, and would account for the suspicion of bile in the urine which was raised in his case.

Sir C. Gordon-Watson has suggested that other gases may have been the cause of the condition. I think this is certainly the case, and that while there may have been some small amount of carbon monoxide present the main cause of the symptoms was probably a methæmoglobinæmia due to the inhalation of one of the other gases formed by the explosion in the confined space.—I am, etc.,

DOUGLAS J. A. KERR, M.R.C.P.

Forensic Medicine Department,
Edinburgh University, Dec 11th

ABDOMINAL CRISES IN CHILDREN

SIR,—I am much obliged to Dr. Robert Richards for calling my attention to the value of tenesmus in the differential diagnosis between intussusception and crises of acute bacillary dysentery. I quite agree that rectal examination is readily tolerated in intussusception, and I ought not to have omitted the mention of tenesmus in dysentery. The question of the presence of fecal matter is evidently merely a matter of adverbs and adverbial expressions. I said that in severe diarrhoea and dysentery some fecal matter is usually present. Dr. Richards says that in most cases of acute bacillary dysentery, soon after onset, the stool consists entirely of blood and mucus. These are not contradictions, and the supply of fecal matter is obviously more strictly limited than that of blood and mucus.—I am, etc.,

London, W 1 Dec 14th

JOSEPH E. ADAMS

TREATMENT OF PUERPERAL SEPSIS

SIR,—In his address on the above subject, reported in the BRITISH MEDICAL JOURNAL of December 12th (p. 1126), Professor Watson states that the benefit of quinine, administered intravenously and intramuscularly, is probably due in many cases to the formation of a fixation abscess. I regret that I cannot agree with this. I have been responsible for the administration of many hundred injections of quinine bichloride during the past few years, and have never yet seen a fixation abscess result. I think it important to give the injection deep into the gluteal region and massage it away from the site of inoculation. Thus, discomfort and pain are avoided and no fixation abscess results.—I am, etc.,

London W 1 Dec 14th

S. GORDON LUKER

POST-GRADUATE EDUCATION IN ENGLAND

SIR,—Certain statements regarding the finances of the Fellowship of Medicine made by Sir Holburt Waring in his address on post-graduate education may create a wrong impression. Sir Holburt stated that the total expenses for 1924 were less than the total receipts by £220 8s. 4d. It might be overlooked that the expenses included a payment of £1,505 in fees for the teaching done. This payment of £1,505 was the net amount paid for teaching, and did not include payment of expenses in connection with the various courses, which expenses were defrayed before the balance available for teaching fees was allocated. Thus the Fellowship of Medicine is distributing about £1,450 in fees. Since its inception the Fellowship has distributed over £8,500 in fees, and as the number of post-graduates is increasing steadily and the attendance at the courses is improving, I think it will be admitted that the Fellowship of Medicine is not such a failure as Sir Holburt would appear to think.—I am, etc.,

London, W 1, Dec 14th

HERBERT J. PATFORD

Always taking a keen interest in the scientific work of the British Medical Association, Powell contributed his share to the discussions at the various annual meetings. At Portsmouth, in 1899, he delivered the Address in Medicine, surveying the recent advances in practical medicine, and discussing, amongst other important subjects, susceptibility and immunity, serum therapeutics, prophylactic inoculation, and the prevention and treatment of tuberculosis. In the discussion at the same meeting on the preventive and remedial treatment of tuberculosis, opened by Sir Clifford Allbutt, Powell, in dealing with insanitary houses as a factor in the spread of the disease, laid special stress on the danger of the common house-fly, which he thought might be potent for harm. He was a vice-president of the

added experience of a generation is the view Powell took of the tubercle bacillus in relation to phthisis. He sums up his consideration of the question thus:

"We cannot say with phthisis as with the more definite zymotic diseases that we have health on the one hand and a specific organism on the other, that when we observe a man sickening with phthisis, the tubercle parasite is already in possession of him, and that we might hope by exterminating the bacillus to eliminate phthisis from our list of diseases. The characteristic lesions of phthisis are brought about by many causes and furnish a soil upon which the tubercle bacillus will readily grow. Epiphytic in nature, concomitant in time, neither the seed nor the fruit of the disease, it must nevertheless be allowed that the tubercle bacillus takes an important part in the extension and conveyance of tubercular lesions."

His own personal experience and observation convinced him that in the ordinary circumstances of life phthisis was not an infectious malady. In a fourth edition, which appeared in 1893, no material change was made in the plan of the work. It continued to be popular, but it was not until eighteen years had passed (1911) that the fifth edition was published, with the title *On Diseases of the Lungs and Pleura, including Tuberculosis and Mediastinal Growths*, in its preparation he was associated with Dr (now Sir Percival) Horton-Smith Hartley. It came at an opportune moment, for much had been done by many workers during the years of its preparation. The British Congress of Tuberculosis had been held in London in 1901, and the second Royal Commission on Tuberculosis, appointed after the Congress, had reported in 1911. The book therefore embodied much important new material and met with a ready acceptance from the profession.

During a discussion in 1899 at the Royal Medical and Chirurgical Society, Powell summarized his views on open-air treatment, a term he thought unfortunate, because it ignored other factors in the sanatorium method, and seemed to suggest that it needed a special building for its application, sanitary or hygienic treatment would, he urged, be preferable as a descriptive term. He recognized, however, that the method was an advance in therapeutics, and that it played an important part in educating the patients for life at home. He expressed his conclusion more fully in a foreword he wrote at this time to the work by Dr Rufenacht Walters on *Sanatoria for Consumptives* (1899). Their usefulness, in his opinion, extended far beyond their immediate purpose of enabling tuberculous patients to get the maximum amount of fresh air, he insisted on their value as educational establishments for teaching the patients self-management, self-discipline, and hygienic laws, and on the importance of the destruction of the tubercle bacilli. He expressed the opinion that sanatoriums are only useful at certain stages of the disease, and urged the importance of giving medical officers of health authority to do much more in regard to consumption than to regulate the sanitation in their districts. A few years later (1902) he was appointed by King Edward VII one of the advisory committee of six to adjudicate in the competition for the erection of a sanatorium to be called after His Majesty's name. The prize was awarded to the late Dr Arthur Latham, with Mr William West as architect, and the sanatorium was built subsequently at Midhurst.

Another work was *On the Principles which Govern Treatment in Diseases and Disorders of the Heart*, founded on the Lumleian Lectures which were delivered before the Royal College of Physicians in 1898 and originally published in the *Journal*. In 1894 he had opened a discussion, at the Bristol meeting of the Association, on the functional diseases of the heart, in an address which showed a wide experience of the subject. The Lumleian Lectures surveyed the whole question of diseases of the heart, and were, like his other work, full of evidence of his careful and thorough methods as a clinician in the matter of trying new methods of treatment, for he related his experience of the treatment of infective endocarditis. Among his other contributions to medical literature were his articles in *Allbutt's System of Medicine* on diseases of the myocardium and angina pectoris. The latter article, concise and to the point, is made more interesting and practical by notes from his case-books. Previous to this he had written articles on physical examination, hæmoptysis, and pneumothorax for *Quain's Dictionary of Medicine* (1882 and 1894 editions),

and on aneurysm of the thoracic aorta and mediastinal tumours in *Reynolds's System of Medicine* (vol. v).

In person Powell was slight, with clean shaven, almost ascetic face, his manner was gentle and deliberate, as was his speech, and his examination of a patient careful and thorough. He had, indeed, a personal charm which appealed to doctor and patient alike. His written opinions, too, were most thorough, and details of treatment were carefully discussed. He married, in 1872, Juliet, daughter of Sir John Bennett. She died in 1909, and in 1917 he married Edith Mary Burke, daughter of the late Mr Henry Wood. He is succeeded by his son Douglas, brevet lieutenant-colonel, late Royal Welch Fusiliers.

Sir HUMPHRY ROLLSTON, President of the Royal College of Physicians, has been good enough to send us the following tribute to his predecessor's memory.

The death of Sir Richard Douglas Powell removes a great figure in the medical world of London, who is successively President of the Medical (1891), the old Clinical (1899-1901), and the Royal Medical and Chirurgical Societies (1904-6), and of the Royal College of Physicians (1905-10), had eminently maintained their dignity and advanced their prestige. During these years of official authority he played an active part in important changes which owed much to his enlightened and hearty co-operation—for example, the amalgamation of the seventeen separate societies with the Royal Medical and Chirurgical Society to form the Royal Society of Medicine in 1907, for it was to him that the late Sir John MacAlister submitted the scheme in 1905, and as a result effective steps were at once taken. The Association of Physicians of Great Britain and Ireland, of which, in 1907, he was the first president, took form under his hospitable guidance in Wimpole Street with the collaboration of Sir William Osler and Sir Wilmot Herrington. He was one of the last of the distinguished band of broad-minded physicians who were so closely connected with Sir William Jenner, and preserved the ideals of medical practice while showing full sympathy with the progressive advances of science. At the Royal College of Physicians he was a dignified and impressive President, and when he felt it his duty did not hesitate to express his opinion as to the right course of action. He had the wide sympathies of a sportsman, and was a courtly gentleman with a most kindly nature.

GEORGE PADDOCK BATE, CBE, M.D., F.R.C.S.P.,
Formerly Medical Officer of Health, Bethnal Green.

We regret to record the death, on December 1st, of Dr G. Paddock Bate, a past-president of the Society of Medical Officers of Health, who from 1875 to 1919 was medical officer of health for Bethnal Green.

George Paddock Bate was born at Leicester in 1843, and from Leicester Collegiate School went to the Westminster Hospital, where he was Chadwick prizeman. In 1865 he obtained the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond., and in 1868 the L.S.A. In 1875 he became F.R.C.S.P., and in the following year took the M.D. Bux. degree with honours in surgery, pathology, and forensic medicine. After serving as house surgeon at the Westminster Hospital he was appointed visiting medical officer to the Manchester Hospital for Sick Children, a post he held for three years. In 1894, when he had been twenty-one years M.O.H. at Bethnal Green, he was appointed surgeon to the J Division of the Metropolitan Police, and so remained until 1920. He was for many years a certifying factory surgeon and a medical referee under the Workmen's Compensation Act, and held the rank of surgeon-colonel (ret.) of the 5th Battalion Rifle Brigade. He was also honorary consulting physician to Queen Adelaide's Dispensary, and medical inspector to Parmiter's Foundation School.

Dr Bate was a keen microscopist, and became a Fellow of the Royal Microscopical Society. His other recreations were chess, and in earlier years lawn tennis. He was for many years a member of the British Medical Association, and in 1907 was a member of the Executive Committee of the City Division. The CBE was conferred upon him in June of this year in recognition of his services to public health.

We have received the following appreciation of Dr Bate from a distinguished member of our profession who knew his work well.

Both the late Sir R C Brown of Preston and Dr G Paddock Bate were closely associated with the Factory Department, the former for fifty-five and the latter for thirty-five years. No factory inspector had been in Preston or East London for more than a week or two without feeling that here was the special medical knowledge of real assistance to him in applying the seriousness of the accidents caused by machinery. Both of them maintained the most cordial relations with successive inspectors, as, indeed, was to be expected, seeing the interest they took in their factory work. Dr Bate, no doubt, also from his position as medical officer of health for Bethnal Green, acted as examiner in sanitary science for many years for posts as inspector of factories. He never ceased to regret that the discontinuance of the requirement of reporting on accidents caused by machinery deprived him of the best means of ascertaining the danger points to life and limb—from which it was his duty to try to safeguard the children whom he had to examine. He must have "passed" at least half a million children and young persons into industrial life—all with a word of encouragement. He used to say, when discussing the question of whether it was worth while to go to the trouble of visiting the place of employment instead of making the children come to his office, that at the factory he could see them with the signs of their occupation upon them, and he could influence employers to concede willingly matters not legally enforceable, once the need or desirability was pointed out to them. Small points, like biting the nails in the handling of lead paint, poisonous drugs, or stains containing potassium bichromate, never escaped him, nor would he permit girls with loose hair, or children with deafness, to work near power machinery. He utilized the power of attaching conditions to his certificates, as to the nature of the work upon which the child or young person should be employed, to the utmost. On the other hand, he used to say that young persons—particularly girls—who attended for examination at his office, away from the factory in their outdoor clothes, earned with them no precise indication of their actual employment, of which, indeed, they were often ignorant. No responsible person attended with them to whom instructions could be given. He was always a protagonist for the certifying surgeon as a field worker in the factory.

SIR HENRY F NORBURY, K C B,

Formerly Medical Director General R N

SIR HENRY FREDERICK NORBURY, K C B, R N (ret.), died at Bitham on December 10th. He was born on September 12th, 1839, and educated at Oundle School and at St Bartholomew's Hospital. After taking the M.R.C.S. in 1860, he entered the navy as surgeon in the same year. In 1868 he took the L.S.A., and in 1870 graduated M.D. Malta. He became staff surgeon in 1872, fleet surgeon in 1879, D.I.G. in 1887, I.G. in 1894, and in 1898 succeeded Sir James Dick as Director General of the Medical Department of the Navy, he retired in September, 1904.

He served in the Kafir war of 1878, in medical charge of the Naval Brigade, was present in the actions at Quoina River and Quintana, was mentioned in dispatches and recommended for promotion. In the Zulu war of 1879 he was again in medical charge of the Naval Brigade, as principal medical officer, was present at the battle of Inyezane, was mentioned several times in dispatches, was promoted to fleet surgeon, and received the C.B. In August, 1879, he was appointed to the charge of the Naval Hospital at the Cape of Good Hope. After three years in that post he was appointed to the charge of the Naval Hospital at Stonehouse. From 1890 to 1895 he was Assistant Director General, and from 1895 to 1898 principal medical officer at Plymouth, ending his career with six years as Director General of the Medical Department of the Navy. In 1879 he won the Gilbert Blane gold medal, in 1882 he received the honorary degree of M.D. from the University of the Cape of Good Hope, in 1895 he was made a Knight of Grace of the Order of St John of Jerusalem, in 1897 he was promoted to K.C.B. at the Diamond Jubilee, in 1900

he received the honorary Fellowship of the Royal College of Surgeons of England, and in 1901 was awarded a good services pension. He was also honorary surgeon to King Edward and to King George, and had the medals given for Queen Victoria's Diamond Jubilee, and for the coronations of King Edward and King George. In 1868 he married the daughter of Mr E G Wade Bowd of Burton Bradstock, Dorset, by whom he had three sons and five daughters. His eldest son is Captain H B Norbury, C.B., R.N., the second is Mr H F O Norbury, Civil Service, and the third is Mr L E O Norbury, surgeon to the Belgrave Hospital for Children and to St Mary's Hospital. His five daughters are all married, three of them to medical men.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

PARLIAMENT will be prorogued on Monday or Tuesday till February 2nd, 1926. Before rising it will have passed the Government of India (Civil Services) Bill and the Safeguarding of Industries Bill.

The county councils, whose views on the draft Poor Law Reform Bill were requested by Mr Chamberlain, will not be able to furnish them before the House reassembles in February. For this reason, and because of other heavy calls on the time of Parliament, the Government has decided that it cannot carry the Poor Law Reform Bill into law next session. It may, however, be introduced late in the session to give the House of Commons an opportunity for discussion.

On December 14th at the House of Commons, Mr Chamberlain (the Minister of Health) met the Unionist party's Health and Housing Committee, with Dr Fremantle in the chair. The Minister explained the scheme of the Poor Law Bill, and showed himself resolved to stand by its principles. He dealt incidentally with the opportunities which it would give local health authorities to assist voluntary hospitals and co-ordinate their work with other public health activities.

About thirty members who support the claim of osteopaths for recognition met at the House of Commons on Tuesday evening and decided to introduce next session a bill proposing that a statutory register of osteopaths should be established, and that this bill should define the educational qualifications to be demanded of osteopaths in Great Britain before registration. At this meeting it was announced that the osteopaths proposed to apply for a charter. There is no confirmation of the recent report that the Government had decided to propose the statutory registration of opticians.

No progress has been made with the Bethlehem Hospital Bill.

The General Medical Council and the "Medical Register"

On December 14th Lieut. Commander Kenworthy asked the Prime Minister if the Lord President of the Privy Council had been approached by any section of the medical profession with regard to the constitution of the General Medical Council and what steps if any he had taken or proposed to take in this matter. Major Hennessy who replied said the answer to the first part of the question was in the negative and the Lord President of the Council considered that the case for action as suggested in the second part did not arise. Mr Basil Peto asked if the Prime Minister would consider the necessity of amending Sections 26, 28, and 29 of the Medical Act of 1858, in view of the obscurity of the procedure under the Act and the confusion of the powers of examining colleges and bodies and the General Medical Council whereby persons whose names had been removed from the Register were required by the General Medical Council to prove that they possessed degrees of which they had been deprived in consequence of the General Medical Council having removed them from the Register before their names could be restored to the Register. Major Hennessy said he was informed that there was no difficulty in interpreting the sections of the Act of 1858 to which Mr Peto referred. It must be remembered that the General Medical Council could not confer medical degrees or qualifications nor could it annul them when once conferred. Moreover it could not place a man on the Register unless he possessed a degree or qualification. When therefore, a practitioner had been deprived of his degree or qualification by the body which originally conferred it that body must restore it before the General Medical Council could reverse its own previous decision. Mr Peto asked whether, when the General Medical Council removed any person from the Register for reasons given the consequence was that the colleges or other examining bodies automatically withdrew that person's degree. If that were the case how could such a person get on to the Register again unless the original examining body acted in the matter? Major Hennessy replied that he must have notice of that question.

Deaths from Erysipelas, and Successful Vaccinations in Infants.—Mr. Serrington, on December 7th, asked the Minister of Health to supply figures giving the deaths of infants under 1 year of age from erysipelas per million births for each year since 1910, the number of infants under 1 year of age successfully vaccinated by public vaccinators in 1914, with the percentage of births, and the total expenditure on public and local funds for each year since 1914 in reply to the first two parts of the question, supplied the following information relating to England and Wales:

Deaths of Infants under 1 year of age from Erysipelas per million Births

Year	Year	Year	Year
1910	167	1915	207
1911	154	1916	146
1912	179	1917	127
1913	161	1918	119
1914	207	1919	91
		1920	149
		1921	133
		1922	124
		1923	112
		1924	116

Number of Infants under 1 year of age successfully vaccinated by Public Vaccinators, and the Percentage of such Vaccinations to the Births Registered

Year ended	Successful primary vaccinations by public vaccinators at the expense of the rates	Percentage to births
September 30th	Number	
1914	284,227	32.2
1915 17	Figures not available	
1918	180,090	27.5
1919	170,653	27.0
1920	241,209	21.8
1921	220,474	25.7
1922	205,106	25.5
1923	234,103	31.0
1924	245,211	33.3

Details of the expenditure on vaccination for 1914 had been given in the report on November 30th.

Vaccination and Small pox.—Mr. Chamberlain stated that in 1924 the deaths of four persons in England and Wales were attributed to vaccination or to causes associated with vaccination. These persons were aged 8, 3, 3, and 5 months respectively. Answering questions by Mr. Bromfield about deaths registered from small pox in foreign countries, Mr. Chamberlain said that in Germany 109 deaths were registered from small pox in 1921, the figure for 1922 was not available. In 1923 there were 17 cases and in 1924 16. The number of deaths in those years were not available. In Italy 16 deaths were registered from small pox in 1916, 114 in 1917, 924 in 1918, 16,380 in 1919, 11,037 in 1920, 1,360 in 1921, 37 in 1922, and 16 in 1923. In Japan there were 889 cases and 212 deaths in 1921, in 1922 the figures were 679 and 124, in 1923, 1922 and 381, in 1924, 1,702 and 266. In reply to Mr. Compton Mr. Chamberlain said vaccine lymph was not tested on rabbits before it was issued to public vaccinators.

Right of Appeal of Insurance Practitioners.—Answering Lieut. Commander Kenworthy, Mr. Chamberlain said he was aware that a considerable section of insurance practitioners desired to be given a general right of appeal in the courts against his decision. He had received resolutions passed at a meeting of delegates, though he could not agree that they represented not less than 5,000 practitioners. He had refused to receive a deputation from the conference as he had already discussed the matter with the Insurance Acts Committee of the British Medical Association, which represented the general body of insurance practitioners. The question was engaging the attention of the Royal Commission on Health Insurance, and he did not propose to take any action pending its report. Inquiry committees, set up to consider whether the continuance of a practitioner on the medical list would be prejudicial to the service were appointed in accordance with regulations made under Section 24 (2) of the National Health Insurance Act, 1924, and were not governed by the provisions of Section 91 of that Act.

Pensions Ministry.—Major Tivon (Minister of Pensions) has stated in reply to questions: (1) That the number of pensioners at present in payment for neurasthenia was about 32,000 of which about 12,000 had been awarded for life. Of the balance, about 17,000 pensioners had been in receipt of pension for four years or more. The possibility of making final awards in these cases was constantly kept in view in connexion with the medical re-examination of cases. (2) That the number of men in receipt of inpatient treatment for neurasthenia in the first week of the present month was 1,809. The yearly cost of the treatment in Ministry hospitals for this class of case was approximately £250,000.

Diphtheria.—Answering Mr. R. Richardson Mr. Chamberlain said that the mortality from diphtheria in West Bromwich was exceptionally high in 1922 and 1923 but the incidence was fairly constant throughout those years and the occurrence presented no feature necessitating any special inquiry by the Minister of Health or reference to the matter in the annual report of the chief medical officer. The high incidence and fatality in 1922 were attributed by the medical officer of health to the fact that in the majority of cases medical assistance was not sought until the third or fourth day of the disease, and there was consequent delay in administering antitoxin. As regards the year 1923 the medical officer of health reported that more prompt recourse to medical assistance, which rendered earlier administration of antitoxin possible, had resulted in a reduction in the case mortality. In 1922, 95 cases were treated

in hospital, of which 18 proved fatal. The figures for 1923 were 153 and 19 respectively. In all these cases antitoxin was administered.

Infant Welfare Centres.—On December 11th Mr. Neville Chamberlain informed Sir C. Oman that he was aware that the infant mortality rate in Market Drayton had generally been in excess of the average rate for the whole country, although this had not always been the case in the past ten years. The county council was taking steps to provide a new infant welfare centre in the district, and further inspection did not seem to be necessary. In reply to another question it was stated that the total maintenance cost of the Wednesbury infant welfare centre was about £225 a year, and of the Wednesbury tuberculosis dispensary about £300 a year.

Arsenic and Apples.—The Minister of Health is trying to arrange that measures shall be taken to remove contamination by arsenical washes before apples are packed for export to this country and has reminded port sanitary and other local authorities of the necessity for strict inspection of apples. Recent analyses have shown the quantities of arsenic on certain brands of apples. The Minister states that poisonous washes are used on apple trees in this country, but the applications are made so early in the season that the risk of any appreciable quantity of poison remaining in the apples, when they are gathered, is negligible.

Fumal in Epilepsy.—Mr. Seurr asked the Minister of Health what steps had been taken to draw the attention of the medical profession to the dangers arising from the use of the drug luminal, especially as, when used for the treatment of epilepsy, serious danger arose if the treatment was continued though the epilepsy was cured. Mr. Chamberlain said the effects of the drug had been fully discussed in the medical press and it seemed justifiable to assume that those doctors who used it were well aware of its action and possible risks.

Industrial Poisoning.—Asked by Mr. J. Baker about the use of varnishes or dopes composed of celluloid or nitrocellulose dissolved in acetone, amyl acetate, or similar solvent, the Home Secretary said he was advised that the existing requirements of the Factory Act had been found adequate so far as danger to health from inhalation of the fumes was concerned. The Chief Inspector was not satisfied about the security from fire or explosion. Answering Mr. Robinson the Home Secretary said 5 cases of lead poisoning were reported in 1921 among pasters manufacturing or repairing electric accumulators, 11 in 1922, 44 in 1923, and 42 in 1924. Since March 1st there had been 15 cases among pasters. The new regulations appeared to have substantially reduced the number of cases. Two cases of carbon bisulphide poisoning had been reported since February 1st and 30 cases of aniline poisoning, but no case of chronic benzene poisoning. The whole subject was receiving special attention from the medical inspectors of the Home Office.

Army Pharmacists.—On December 8th Captain D. King stated that all army dispensaries were under the direct supervision of a medical officer. The only persons, other than medical officers, who might make up prescriptions in those dispensaries were qualified army dispensers and they might only make up prescriptions signed by a medical officer. He was not aware of any reason for considering that the present procedure was not satisfactory. It was not the case that a superintending pharmacist was now in subordinate charge of the dispensary in every military hospital of one hundred beds and over. The War Office had advised the Central Voluntary Aid Detachment Council who consulted them on the subject that the status of pharmacists in their detachments should not be higher than that of non-commissioned officers in the army. The reason was that the status of members of Voluntary Aid Detachments should be appropriate to the duties they might be required to perform in war. There were no appointments of officers' rank for pharmacists in the army. He would not be justified in giving instructions that quartermasters in the British Red Cross Society, whose duties it would be to order and superintend the distribution of medical supplies in war, should be qualified pharmacists.

Death Statistics of Seamen.—On December 15th Sir P. Cunkiff (President of the Board of Trade) told Mr. Watts that he had received a resolution from the Royal Sanitary Institute and also its detailed suggestions regarding the death statistics of seamen. The Permanent Consultative Committee on Official Statistics had appointed a special subcommittee to advise whether any alteration in the classification of these death statistics was necessary.

Notes in Brief

Giving particulars of accommodation in Naval Hospitals, Mr. Davidson (Parliamentary Secretary to the Admiralty) said in reply to General Charteris that the average daily numbers of patients in these hospitals for the period January 1st to September 30th 1925 were: Haslar 334, Plymouth 375, Chatham 377, Portland 50, South Queensferry 44, Malta 188, Bermuda 22, Hong Kong 51, Cape 36, Wei-hai-wei 11. No later information was available.

Meeting the Unionist Agricultural Committee at the House of Commons, on December 9th Mr. Chamberlain said there was no intention of passing the Poor Law Reform Bill into law during 1926 though it might be introduced late in that session, purely for discussion.

The Minister of Transport is considering the question of asking for additional powers to deal with dazzling headlights, in the Road Vehicles Bill which he hopes to introduce.

The Secretary for Scotland has stated that no local authority in Scotland so far as he was aware, made a charge to tuberculosis patients or their relatives for sanatorium or other treatment provided by the authorities.

Medical News.

In our issue of December 5th we published a review of the new fourth edition of the late Sir James Mackenzie's *Diseases of the Heart*, and in the same issue (p 1075) referred to it in the course of a leading article entitled "Mackenzie's Last Work." Messrs. Faber and Gwyer inform us that there is still another book by Sir James Mackenzie to come. It is a short book, or perhaps more correctly, as they tell us, a long essay, which they intend to publish under the title *The Basis of Vital Activity* early next year. It deals with the conclusions he drew from researches in the institute at St. Andrews, now known by his name.

THE Royal Sanitary Institute will celebrate its jubilee next July by an Imperial Congress in London, of which Mr. Neville Chamberlain will be president. The Lord Mayor and Corporation of the City of London have granted the use of the Guildhall for the opening meeting. The congress will have six sections and seven conferences. The Lord Mayor will be chairman of the conference for sanitary authorities, Sir George Newman of the section of sanitary science and preventive medicine, Sir William Hardy, F.R.S. (Director of the Food Investigation Board), of the section of the hygiene of food, Sir William J. Collins of the conference of sanitary inspectors and Dr. G. F. Buchanan of the conference of medical officers of health. Official representatives to attend the congress have already been appointed by Australia, New Zealand, India, the Straits Settlements, and by the Spanish Government.

A BALL in aid of the Royal Medical Benevolent Fund Guild will be held, under the patronage of the Princess Louise, Duchess of Argyll, at Kensington Town Hall, on Tuesday, January 12th, 1926. Tickets (15s. each or 6 for four guineas) can be obtained from the Honorary Secretary, 20, Upper Phillimore Place, Kensington, W 8.

THE Fellowship of Medicine announces that a special vacation post-graduate course will be held at the Prince of Wales's General Hospital from January 11th to 23rd, 1926. Demonstrations of modern clinical methods will be given each morning, and in the afternoons special lectures will be delivered and there will be practical work in the various departments of the hospital. From January 4th through out the month a series of lecture demonstrations on psychological medicine will be given at the Bethlem Royal Hospital on Tuesdays and Saturdays at 11 a.m. At the West End Hospital a month's course in neurology will open on January 4th at 5 p.m. The North Eastern Hospital will hold a three weeks' course in infectious fevers on Wednesdays at 2.30 p.m., and Saturdays at 11 a.m., from January 11th, and there will be a course in diseases of children at the Queen's Hospital from January 18th to 30th. At the National Hospital for Diseases of the Heart a whole day course will be arranged from January 18th to 30th. It is proposed to hold weekly demonstrations in clinical surgery throughout the year. Those arranged for next month are: January 11th, Mr. Munro at St. Mark's Hospital, 5 p.m.; 19th, Mr. Souttar at the London Hospital, 2 p.m.; and 27th, Mr. Carling at the Westminster Hospital, 2 p.m. The Fellowship has arranged a further series of lectures from January to March. The first will be given by Dr. Herbert Spence on abdominal palpations in pregnancy, on January 21st, at 5 p.m., in the hall of the Medical Society of London. A copy of each syllabus and of the Fellowship general course programme may be obtained from the Secretary, 1, Wimpole Street, W 1.

THE People's League of Health, of which the King is patron, has arranged a series of lectures for the coming year, beginning at the end of January. Among the lecturers are Sir Frederick Mott, Sir Maurice Craig, Sir Robert Armstrong, Jones Dr. Bernard Hart, Dr. A. F. Tredgold, Dr. T. Beaton, Dr. R. H. Cole, Dr. W. A. Potts, Professor Leonard Hill, Professor Mellanby, Sir Henry Gray, and Professor F. F. Wynne. The lectures will be given at the house of the Medical Society and the Regent Street Polytechnic. Particulars can be obtained from Miss Olga Nethersole, R.R.C., 12, Stratford Place, W 1.

THE annual dinner of the Medico Legal Society was held at the Holborn Restaurant, London, on December 11th. Earl Russell (a past president) took the chair in the absence of the President, Lord Justice Atkin. Sir St. Clair Thomson, President of the Royal Society of Medicine, in responding to the toast of the medical and legal professions, proposed by Lord Riddell, made amusing reference to the "irregular relationship" between Medicine and Law which (like all liaisons) had its features of interest. "We doctors," he said, "trust and envy, but do not understand lawyers, if we understood them, perhaps we should not trust them so much." Mr. T. R. Hughes, K.C., chairman of the General Council of

the Bar, responding for the Law, spoke of the high regard felt by lawyers for the medical profession and their appreciation of its great assistance in the administration of justice. Sir Emley Blackwell, Legal Assistant Under Secretary of State, Home Department, also replied. The chairman, in submitting the toast of the society, mentioned the proposed foundation of a medico-legal institute, to which reference was made in these columns on June 27th last (p. 1184). It was hoped, he said, that considerable progress with the scheme would be made in the near future. In a passing allusion to recent criticisms of the General Medical Council in the lay press, Earl Russell remarked that public opinion as expressed by the man in the street was about the least competent body to decide on the standards of conduct necessary among members of a profession. The toast of "Our Guests" was proposed by Sir Bernard Spilshury, joint honorary secretary of the society, and responded to by Dr. Vincent Dickinson, Master of the Society of Apothecaries, and Sir Alexander Renton, formerly Chief Justice of Ceylon.

THE forty-sixth annual meeting and dinner of the Old Epsom Club was held on December 10th at the Procadero Restaurant, Mr. J. S. Cotman in the chair. The toast of "Florest Lpsomia" was proposed by the chairman and the headmaster, Mr. A. O. Powell, in his reply, drew attention to the "record" attendance, and gave an account of the various successes of the year. During the evening Mr. S. Maynard Smith, O.B., F.R.C.S., for many years honorary secretary of the club, was presented with a cream jug of the 1735 period, for which a large number of subscriptions had been received from all parts of the world. The toast of "The Visitors" was proposed by Mr. Maynard Smith, and was responded to by Sir Humphry Rolleston, who acknowledged the great debt owed by the medical profession to Epsom College.

AT the annual dinner, on December 10th, of the British Serbian Units Branch of the British Legion, Sir James Purves Stewart occupied the chair, and was supported by Professor Louise McIlroy, Sir James and Lady Berry, Dr. Alice Hutchinson, Miss Nina Boyle, Sir William Simpson, Miss Flora Stades, and the Serbian Minister in London. About 120 guests were present, and all civil and military units were represented.

THE late Mr. James Shorrocks of Bowdon, Cheshire, has bequeathed £2,000 each to the Manchester Royal Infirmary and St. Mary's Hospitals, Manchester, and £1,000 to the Altincham Provident Dispensary and Hospital. His wife having predeceased him the sum of £100,000 is to be divided between eight legatees and the hospitals mentioned above in share proportionate to the amounts of the legacies already given to them.

AT the meeting of the Court of Governors of the London Hospital, on December 9th, it was stated that Her Majesty the Queen had consented to become president of the hospital in succession to the late Queen Alexandra. Viscount Knutsford also announced the receipt of a gift of £50,000 for research work from a donor who desired to remain anonymous.

THE annual report of Livingstone College for the year 1924-25 opens with a reference to the loss sustained by the death of Dr. C. F. Harford, its founder and first principal, of whose work an appreciation appeared in our issue of July 11th. The report contains several letters from old students showing how the elementary medical training given them at Livingstone College had been of assistance in their missionary work. During the year nine students had entered for the whole nine months' course, one for the six months', and twelve for periods of one to five months. The vacation class in July was attended by thirty-two students, and forty-two others entered for the short courses on care of the health in the tropics. As a memorial to Dr. Harford an effort is being made to raise a capital sum of £3,500 in order to supplement the college funds.

AN oto-neuro-ophthalmological society has recently been founded in Paris, with Dr. Andrieu Thomas as president and Dr. Baldeuwick as secretary. Its organ will be the *Revue d'oto-neuro-oculistique*.

M. PIERRE DUVAL, professor of surgical therapeutics in the Paris faculty, has been elected a member of the Académie de Médecine in the Section of Surgery.

A MEETING of the Parliamentary Medical Committee, which included Lord Dawson of Penn, resumed on December 16th a discussion on the General Medical Council and on the processes of striking off practitioners from the *Medical Register* and reinstating them. The Committee felt that the position and responsibilities of the Council were not fully understood by the public, and approval was given to a suggestion that next session lay Members of Parliament should be invited to meet the Medical Committee and hear explanations. No suggestion was made that the constitution or powers of the General Medical Council required revision.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **British Medical Journal** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **British Medical Journal** must communicate with the Financial Secretary and Business Manager, British Medical Association House Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the **British Medical Journal** are MUSEUM 9561, 9562, 9563, and 9564 (internal exchange four lines).

The TELEGRAPHIC ADDRESSES are

EDITOR of the **British Medical Journal**, *Antiology Westcent London*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent London*

MEDICAL SECRETARY, *Medisecra Westcent London*

The address of the Irish Office of the **British Medical Association** is 16 South Frederick Street, Dublin (telegrams *Bacillus Dublin*, telephone 4737 Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams *Associats, Edinburgh*, telephone 4361 Central).

QUERIES AND ANSWERS

ECHINOCOCCAL CYSTS IN A CAMEL

Dr J C MILNE (Hurghada, Egypt) reports the discovery of two cysts of *Taenia colonicocis* in the lungs of an old camel. The outer walls of the cysts were thick and fibrous, with a white, easily broken, lining. One cyst was filled with a clear fluid, the other contained a gelatinous material, with some calcareous fragments and numerous hooklets. Dr Milne asks whether this condition is common in camels. He has found in medical textbooks no report of its occurrence in them.

AN ERRATIC CASE OF DIABETES

Dr J RICKARDS (Banbury) reports a very erratic case of diabetes, in which the symptoms vary so rapidly even from hour to hour, that a suitable régime is difficult to devise. On one day the patient is free from all symptoms and the pulse rate never exceeds 80; on another day the pulse rate may reach 120 and never be lower than 100, though the afternoon sample of urine may be absolutely free from both acetone and sugar. For about a year this patient has been kept fairly well on a carefully restricted diet with occasional egg and vegetable days, insulin being given in doses of 12 to 14 units in the morning and 4 to 5 in the evening. Recently he developed inconstant symptoms of acidosis: a very rapid pulse, some air hunger and general malaise relieved by moderate exercise. His wife also has detected an odour of acetone occasionally before breakfast. The patient is a tall, spare man who has maintained his average weight and before this attack could take his daily walk of four or five miles with full enjoyment and vigour. He has, however, been troubled by attacks of rapid pulse and other signs of acetone poisoning the worst time being usually when resting after breakfast. Exercise almost invariably slows the pulse. He takes very little fat, and very readily gets attacks of hypoglycaemia with insulin especially if the evening dose is much increased. Only a weak reaction to Rother's test has appeared in the morning urine and none in samples taken later in the day. Benedict's test for sugar produced a yellow precipitate in the morning specimen while the afternoon and evening specimens were quite free from sugar. The most recent tests have given an acetone reaction in both morning and evening samples and even in sugar free specimens. This specific gravity of samples is quite normal, and also the daily quantity. He does not suffer from thirst.

Dr Rickards asks if there is any relation between the presence of sugar and acetone in the urine and blood, and if not what is the cause of acetone in this case? Also, does insulin antagonise acetone formation as it does hyperglycaemia? This problem is the notable tendency to acidosis in the absence of sugar and other symptoms of diabetes. Increasing the carbohydrates in the diet effected some improvement but the acetone is eliminated very slowly. Further increase in insulin is precluded by attacks of hypoglycaemia.

INCOME TAX

Rents of Property in the Irish Free State

"Puzzled" owns property in the Irish Free State the gross rental of which is £100 per annum and the fixed charges, agent's fees and deduction of Free State tax amount to £50. What amount should be returned for assessment to British income tax?

The expenses referred to are deductible if they are payable in the Irish Free State, but not the income tax. On the

other hand, an allowance can be claimed in respect of that tax from the duty charged at the standard rate on the income. Particulars of the Irish Free State tax paid should be given with the return for assessment, in order that this proper allowance can be made.

LETTERS, NOTES, ETC

INFLAMMABLE HAIR COMBS

Dr CECILY M E MAUDE (Oxford) writes with reference to Colonel Lillott's letter (December 5th, p 1089). "An elderly relative (not under my own care) recently set fire to her hair combs by accidentally coming too near a lamp. The burns are deep and rather extensive, and at the present rate of progress she will hardly be restored much before Easter."

RECURRENT URTICARIA

Dr G CRAIGIE BELL (Frinton-on-Sea) sends the following observations with reference to the inquiry by "N L," published in the **JOURNAL** of November 21st (p 984).

J N, male, labourer aged about 35, a pauper patient had for many years suffered from attacks of urticaria. Fork in any form, many forms of fish shrimps and cockles, would always be followed by a pretty severe attack. In March 1922 he had a severe attack of what is generally called rheumatic fever, temperature 104°, profuse acid sweating, intense pain and swelling in most joints, and pleurisy. This lasted some weeks. On recovery he was most careful in his diet and yet had some attacks of urticaria. In May, 1923 he had another acute attack of rheumatic fever with the same symptoms as before, plus pericarditis. He again recovered and very soon had the most awful attack of urticaria that I have ever seen. Nothing did him any good, alkalis, calcium lactate, salol, kerol and aperients were useless. At the end of a fortnight he was so hot from want of sleep that I sent him to the Colchester Hospital for an opinion. He seemed so ill that he was kept in for about a week and then discharged, no better. I then wrote to Sir Kenneth Gosday, who said the case was almost certainly one of streptococcal poisoning, and sent me a vaccine of polyvalent streptococci of the strains most likely to be useful—namely *pyogenes*, *proteus*, and *teniculous*—and said that if no good followed he would examine the man's faeces chemically and bacteriologically. The result of the vaccine was an immediate improvement in less than a fortnight the man was well and he has so continued ever since. He comes to see me about four times a year and has an inoculation. He eats anything and everything, and has never had a suspicion of a recurrence. I presume the rheumatic fever was an acute streptococcal infection, which left the man with a lowered resistance to intestinal toxins, from which he had suffered for many years.

CANCER AND PNEUMONIA

APPROPOS of the case reported by Dr E I Spriggs (**BRITISH MEDICAL JOURNAL**, November 14th p 873), Dr Charles J Hill Aitken (Kilnthurst, Lorks) writes: "An elderly man subject to attacks of diarrhoea of which he was sure he knew the cause passed through what I called acute primary pneumonia. His pneumonia was not quite so type and his consolidation took two months to clear up. He returned to his work, but complained of being easily tired. His diarrhoea still occasionally bothered him, but not his chest. A few months later he had acute abdominal obstruction, and, as I expected, inoperable cancer was palpable from the rectum. Presumably his 'pneumonia' was closely connected with the cancer, which was then growing, but which had not been diagnosed."

THE "GRASSENDALE" DIET SHEET

WE have received from Mr S G Willmott Ph D, B Sc, and Mr Frank Wokes, B Sc, of Grassendale a diet chart for the use of patients whose food has to be carefully watched. For each article of diet it gives the percentage composition in carbohydrates, proteins, and fat the energy value, the essential elements, and approximate vitamin content. All ordinary foods are represented in this list, in fact, we find everything that middle class people are likely to want to eat. These charts can be purchased at 6d each or less for large numbers, and special terms are promised to hospitals. The scheme adopted is very simple but some knowledge of dietetics is necessary to get the best out of a chart like this. We suggest that most people would like to be told again how much 1 oz by weight or measure equals in grams and also how much the average hen's egg weighs. One difficulty not solved by such a chart as this is the ratio of edible portion of food to total as purchased and we presume that the authors assume knowledge of this in the kitchen. But these are minor points. The chart is an excellent piece of work and will be most useful in guiding dietary. The authors' notes on the back are sound and in keeping with the latest research. Orders for copies should be sent to Messrs Willmott and Wokes, Grassendale, Liverpool.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 45, 48, 49 and 50 of our advertisement columns and advertisements as to partnerships assistantships and locum tenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 220.

An Address ON BACKACHE IN WOMEN

BY

HENRY RUSSELL ANDREWS, M.D. F.R.C.P.,
SENIOR OBSTETRIC PHYSICIAN, LONDON HOSPITAL

When I started writing a few preliminary notes on the subject given me by your secretary—namely backache in women—I was faced at once by the question: Was I to attempt a scientific and orderly review of all the varieties of backache, with their causes, diagnosis and treatment, or was I to talk about backache in a much more informal way, discussing the common causes, the differential diagnosis of cases of backache as met with in ordinary everyday practice, pointing out some of the most likely pitfalls for the unwary who omit to make as thorough an investigation as they can, and to tell you what treatment I have found most successful? I chose the latter, and hope that I have done right.

Backache is one of the commonest complaints of women in fact, one lady member of our profession has said that women may be divided into two classes—namely, women with backs and women without them. The following is a rough and ready classification of some of the causes of backache which will be of some use for our purpose to-day, and will avoid some needless repetition.

Definite disease or injury of some of the tissues of the back.
Fatigue without abnormal physical signs.
Enteropneustic.
Abdominal tumours.
Carcinoma of the uterus.
Carcinoma of the rectum.
Disease or infection of the kidney.
Retraction of the uterus.
Prolapse.
Chronic pelvic inflammation.

There is nothing to prevent a patient from having at the same time troubles coming under more than one of these headings. This is a very important matter from the point of view of treatment, and will be referred to later.

Disease or Injury of some of the Tissues of the Back

This is a very large class of cases, including among others curvatures of the spine, secondary malignant growths, toxic meningitis, injury or disease of the sacro-iliac or sacro-coxal joints, bruising or tearing of muscles, etc. This class emphasizes the importance in the diagnosis of backache, of not trusting to abdominal, vaginal, rectal, and bimanual examination alone, but examining the back itself as well. It does not take long to examine the back, the important points are: Is there any limitation of movement or rigidity in any part of the back? Is there tenderness of any part of the back made worse by pressure? Is there any tenderness of the sacro-iliac or sacro-coxal joints, with pain on passive movement?

I saw last year a patient aged 36 from whom I had removed a tuberculous pyospinus eight years previously. She was complaining of lumbago and sciatica and was being treated by massage and electricity. Examination of the back revealed definite rigidity, and an x-ray examination showed caries. Instead of massage and electrical treatment she was treated by a spinal splint grafted on from the tibia, and a plaster jacket, with the happiest results.

If a patient can touch her toes without bending her knees, bend over backwards and to either side and can stand being gently thumped all over her back without pain, disease of the spine can be excluded, but if anything in this examination causes suspicion that there may be spinal disease an x-ray examination should be made.

Meningitis of the roots in women is rare and would probably be fairly easy to diagnose.

If there is a secondary malignant growth involving one or more of the vertebrae there will be evidence of a malignant growth elsewhere, or a history of removal of the breast or uterus, or some other operation for malignant disease some time before. The severity of the pain in

these cases is usually far greater than that of the common lumbago of women.

Disease of the sacro-iliac joints is rather rare. Unless it is advanced, definite proof of its presence cannot be obtained without an x-ray examination. Injury or strain of these joints, however, is more common, sometimes is the result of labour sometimes as the result of a fall. In such a case the pain and tenderness are localized to one of the sacro-iliac joints, and the pain is increased by pressure on the iliac crest and by an attempt at passive movement of the iliac bone on the affected side. The best treatment is counter-irritation combined with firm stripping of the affected side of the pelvis. In many cases of so-called "chronic lumbago"—I say advisedly "so-called"—the pain is localized to the sacro-iliac joints, although there is no evidence of injury or disease of these joints, and there are no abnormal physical signs to be found elsewhere. Massage, heat, bending exercises, and a potassium iodide mixture will often effect a cure.

Backache due to tearing or bruising of muscles of the back is not nearly so common in women as it is in men, but it occurs occasionally after some usually violent effort lifting a heavy weight, or after a fall. A tender spot is found, firm pressure on which aggravates the pain rather than relieving it—just the opposite to the effect of firm pressure on a back which aches only from fatigue. I can speak from personal experience of the effect of stripping on such a back, after a heavy hunting fall. Before the application of stripping I felt that I was crippled, and hardly dared to move my back, but after being stripped I was able to operate and do anything I wanted in comparative, if not absolute comfort. I understood then that the "old physios" which I had applied to the backs of libonics in the receiving room of the London Hospital in days gone by had possibly had more than a mental effect.

Fatigue

A very large number of the chronic backaches of women are due to fatigue of the back muscles, often increased by weakness of the abdominal muscles and the consequent distension of the abdominal viscera, which sag down when they are deprived of the support normally given by a sound abdominal wall. Such patients are often multiparous, in whom the effects of rapid child-bearing, with hard work, insufficient rest, nights broken by attention to the needs of babies and young children, insufficient amount of fresh air, often chronic constipation, insufficient nourishment on account of bad teeth, etc., possibly on top of a poor muscular development, result in exhaustion with chronic backache. Some of these patients say that they always get up tired. Sometimes the backache is relieved by rest in the recumbent position, but some of them say that the backache keeps them awake. To label these patients as neurasthenics does not help matters. As the late Sir Clifford Allbutt said (I forget his exact words), they have a general asthenia. Some of these patients have enteropneustosis, many of them have loose kidneys, and many of them have some uterine and vaginal prolapse on account of the weakness of the pelvic floor. That they should have loose kidneys is only to be expected, as the packing of fat round the kidneys has been absorbed, but the low position of the kidneys alone will do little or no harm unless the patient is told that she has a floating kidney. I think that "floating kidney," like "ulcerated womb," is a term that should never be used to a patient. Patent medicine advertisements have so convinced the public that anything wrong with the kidneys is a cause of pain that a patient who is told that she has floating kidneys must be unusually strong-minded not to brood over this disaster and to imagine pain if she has none, and to exaggerate any pain that she has. Her women friends will sympathize with her and tell her horrible stories of the effects of floating kidneys. Unless there is torsion of a loose kidney causing constriction of the vessels or merely a rare condition—the low position of the kidney is usually of very little importance. Excision operations for loose kidneys, nephropexies, which used to be performed frequently twenty years ago, have almost died out. Ventral suspension or ventral fixation for retention of a slight degree of prolapse in women with

prolapse of most of the abdominal contents, and, fortunately, rapidly dying out as well. It used to be fairly common to see a worn-out multipara with sagging abdomen and chronic backache who had had one of these operations performed, with wonderfully successful result until she returned to her household duties, but with no permanent benefit.

The ideal treatment would be a long course of rest, largely in the open air, with massage and guided movements, and attention to all the points which had been neglected in a busy, unselfish life, but this can seldom be carried out. A well fitting abdominal belt, however, will often alter a woman's whole outlook on life. If examination of the abdomen is made with the woman standing up—the only way to examine the position of the kidneys—it will often be found that if the examiner stands behind the patient and lifts up the lower abdomen with both hands she will say at once that that gives her exactly the feeling of support which she needs. The belt must fit properly, be sufficiently deep from above down in front, take its support from the back, and lift up the lower abdomen. A few patients find extra relief from kidney pads, but their use as a general rule has been given up, as they are usually found to be unnecessary. In some cases they do harm. I have seen two or three patients who said that they were more uncomfortable after being supplied with a belt than before, and the explanation was simple—namely, they put on the belt when they were standing up and carelessly pressed in the kidney pad above the kidney instead of below it. If the belt has a special kidney pad the patient must be shown how to apply it, lying down on her back and sitting the pad below the kidney.

Some of these fatigued backaches begin before marriage in girls of poor muscular development who get no outdoor exercise of any sort after they leave school. The so-called upper classes have had drilled into them at school the importance of exercise and of keeping fit, but there is an opportunity of doing some useful work in preventive medicine in the education of work-girls, shop-girls, city typists, etc. Very many of these girls have to leave home early after a hurried breakfast, with no time for a habitual evacuation of the bowels, travel to their work by train, trolley, or omnibus, spend a long day sitting over a desk or standing, and arrive home, after having a minimum of fresh air too tired to go out again. In some of them the nature of their occupation is peculiarly liable to bring on backache—for example, sitting at and bending over a low desk or table for many hours at a time. If they marry when they are slender, with poor muscular development, anemic, and chronically constipated childbearing is only too likely to result in general fatigue with chronic backache. They ought not to have to pay this high price for maternity. Girls' clubs, with their gymnastics, Swedish exercises, and dancing, if tennis and other outdoor games are impossible, can do a great deal to improve the physique of these workers but many girls will not join them, or find that home duties make it impossible for them to join them. If such girls can be made to believe that chronic constipation is a thing to be ashamed of, that it ought not to be treated entirely by drugs, and that exercises with the help of taking much more fluid will do much to combat it, and that a visit to the water-closet ductly after breakfast is one of their most important appointments in the day, their physique will improve and their work will not make them too exhausted to be able to take some outdoor exercise when it is over. Swedish exercises, especially those which excite the abdominal muscles, skipping, and abdominal massage before dressing, will improve the condition of these girls and enable them to start the day with a feeling of *bien-être*. But even if they have the inclination to try this simple treatment they may say that they have neither the room nor the time for it.

High-heeled shoes are sometimes blamed for backache. It is probable that many men who wore high-heeled shoes would complain of backache, chiefly because he had fallen to them suddenly and had to alter his balance, but the fact remains that the majority of girls and women who wear them are free from this trouble. My colleague, Mr. Robert Milne, tells me that an addition of half an inch to a woman's heels will sometimes do a good deal to relieve her backache.

Intoxication

Taken together with, or apart from, the fatigue element backache may be caused by anteopiosis and by enlargement of the abdomen from any cause. Pregnancy, especially in multipara, is a frequent cause of backache which makes the housework an effort and the woman's life during the last few months of pregnancy a miserable one. It is surprising to me that so few women wear abdominal belts during pregnancy. Unless a multiparous woman has unusually good abdominal muscles it must be a conservative measure to give them some artificial support. A well fitting belt will not only give much comfort during the later months, but, by preventing undue stretching of the weak muscles, will give a much better chance of recovery of tone of the abdominal muscles after labour. I cannot resist the temptation to stray a little from my subject—it is not really straying, as we cannot consider the subject of backache without paying some attention to prophylaxis—and to say a few words about prevention of a pendulous condition of the abdomen. Every woman ought to have her abdominal muscles massaged during the puerperium from about the sixth day onwards in a normal case. If the nurse is a trained masseuse so much the better, but any intelligent woman can be shown in a few minutes how to massage the recti and oblique muscles. Massage, for ten minutes or so daily, will make the puerperal woman more comfortable, will help her to avoid flatulence and constipation, and will increase her chance of recovering the tone of her abdominal muscles. The use of a stiff binder should be forbidden and patients should be encouraged to carry out bed gymnastics.

Tumours, Obesity

It is obvious that large ovarian and uterine tumours may cause backache by their weight, without any inflammatory changes, as may also a large collection of free fluid, and we need not say any more about these. Much smaller tumours, such as uterine fibroids or ovarian dermoids, impinged in the pelvis, may cause backache, as well as bearing down pain if they extend deeply into Douglas's pouch.

Very fat women, who find walking difficult and cumbersome, frequently complain of backache. They are caught in a vicious circle—the less they walk the fatter they become and the fatter they become the less they will. In some of them an abdominal mass of adipose tissue weighing 2 or 3 stone can be lifted up. If this mass is held up by a belt they may become much more active, with great benefit to their health and comfort.

Carcinoma of the Uterus and of the Rectum

In some cases of carcinoma of the uterus backache may be of almost intolerable severity. Unfortunately, when pain in the back is present with carcinoma of the uterus the growth has usually advanced beyond the limit of surgical aid. One still sees patients with continuous bleeding whose doctors say that they had not made a vaginal examination because they saw no indication for a suspicion of carcinoma, as there was no wasting, no pain, and no offensive discharge. It cannot be emphasized too strongly that these clinical symptoms only too often indicate that the carcinoma is no longer confined to the uterus and that radical operation is impossible, and to wait for these symptoms before attempting a diagnosis is in many cases to wait until too late.

There is no time to say more about carcinoma of the rectum than that it must be suspected when the patient complains of severe backache from "piles," and that rectal examination is imperative in obscure cases of pelvic disease.

Discussion on Infection of the Kidney

About renal calculus and tuberculosis, and renal carcinoma I do not propose to say anything, as I see these conditions so seldom. Pyelitis or pyelonephritis, due to infection with the *Bacillus coli communis* is an exceedingly common condition, and is often missed until the patient has suffered from it for a long time, while she has been having treatment for various conditions which might have caused, but did not cause, the backache. If the condition is acute or subacute the character of the pyrexia is often most suggestive. There are few other conditions in which a patient, a few hours after a severe rigor, with a temperature of 104° or so, looks well, feels well, and has a normal

or only slightly increased pulse rate. Haematuria is common in these acute and subacute cases. In many cases, however, there is little or no pyrexia, and no symptom beyond backache. Careful examination may reveal that one kidney, usually the right, is tender, and that there is tenderness along a line from the kidney to the iliac fossa, along the line of the ureter. The urine, which is always acid in reaction, may show nothing wrong on naked-eye examination, or there may be a small deposit of pus or debris when it has been allowed to stand in a conical glass, there may be an opalescent appearance, and there may be a trace of albumin. Bacteriological examination of a catheter specimen, drawn off into a sterilized bottle, will show the *B. coli communis*. It was thought, a few years ago, that pyelitis due to *B. coli* was specially common in pregnancy, but it is now known that it is extremely common apart from pregnancy. It is so common that bacteriological examination of the urine has become part of the routine examination of cases in which pain in the back is complained of and no evident cause can be found on a thorough physical examination. The treatment is simple, and, in most cases, successful in a short time. The patient must be confined to bed and kept warm, must drink large quantities of harmless fluids, and must take potassium citrate and sodium bicarbonate in moderate-sized doses sufficiently frequently to render the urine alkaline. The common practice of giving hexamine and acid sodium phosphate cannot be recommended. Pain is often increased by this acid treatment in spite of the diuresis produced by it. As soon as the urine has become alkaline the pain and pyrexia disappear in the large majority of cases. The treatment is then gradually relaxed, the urine being kept alkaline for some weeks. In only a very small proportion of cases is catheterization of the ureter with lavage of the renal pelvis necessary.

Retroversion of the Uterus

We come now to a matter on which there has been, and still is, much controversy. Some look on almost every case in which the uterus is turning backwards as a case for operation. At the other end of the scale are some who contend that retroversion of a normal-sized, freely movable uterus is never of any importance, and that any symptoms which may accompany it are the outcome of neurasthenia. The safe course lies between these two extremes. There is little difference of opinion about cases in which the retroverted uterus is fixed by pelvic inflammation, usually the result of salpingitis. Everyone agrees that in many of these cases there is persistent backache, increased on exertion and before the monthly periods, and that if medical measures fail, as they usually do, an abdominal operation is called for, with removal or freeing of the tubes, and slinging the uterus up in a position of anteversion. In my opinion retroversion of the uterus without any fixation is sometimes responsible for backache. I do not find, as some do, that retroversion is the cause of backache in young single women, but I find a few cases in puerperal women in which backache is apparently caused by retroversion of a rather bulky uterus. The backache is worse before the periods, and there is dyspareunia. The proof that the retroversion is the cause is that if a pessary keeps the uterus anteverted the backache disappears and does not return unless the retroversion recurs. In two or three cases every year I advise a round ligament operation, sometimes after a preliminary trial of a pessary, and I find that the permanent results are good. In these cases there is some subinvolution. I do not believe that uncomplicated retroversion in young single women and in the elderly causes backache or calls for operation. I think that the cases of retroversion of the uterus which cause backache would become less common if more care were taken during the puerperium to prevent retroversion. Distension of the bladder and fullness of the rectum cause retroversion and should be avoided. Before the patient gets up a pelvic examination should be made, and, if the uterus is retroverted, a ring pessary should be inserted after the uterus has been manipulated into the normal position. The pessary inserted during the puerperium will have a curative, not only a palliative, effect, and when it is removed

at the end of three months the uterus will probably be found to remain in the normal position.

Many patients are accused of having retroversion of the uterus and are given useless and possibly painful pessary treatment on a wrong diagnosis. I have been struck by the number of cases in which I have been told that rectal examination proved that the uterus was retroverted because the uterus could be felt bulging into the rectum, whereas what was felt "bulging into the rectum" was the cervix, which was pointing downwards and backwards as it should. If rectal examination of a normal pelvis is made the cervix will always be felt easily, and when the rectum is converted from a potential into a positive cavity by the examining finger the cervix appears to press against the anterior wall.

Prolapse of the Pelvic Contents

In some cases of prolapse there is a good deal of backache, though it is not usually the chief complaint, and some patients with complete prolapse are free from backache. A word of warning must be given once more against concentrating on treatment of weakness of the pelvic floor or retroversion of the uterus in cases in which almost all the abdominal viscera as well as the pelvic organs are sagging down. Results of colporrhaphies and ventral fixation are sometimes extremely disappointing to the patient in these circumstances. Prophylaxis is as important as treatment of prolapse. Patience in the conduct of midwifery, avoidance of too early rupture of the membranes, waiting until the os is really fully dilated and the edge of the cervix pulled up, or, in some cases, pushed up above the presenting part, not simply dilated sufficiently to allow of application of the forceps, gentle traction in the right direction rather than forcible pulling if the forceps must be used, and immediate repair of lacerations, will do much, though not all, to prevent prolapse. I say "not all" because I see a few cases of prolapse, only a very small proportion, in which there has been no difficulty and no interference in labour. It is possible that general use of pelvic-muscle gymnastics during the puerperium will still further diminish the frequency of the occurrence of prolapse.

Conclusion

Lack of time prevents me from discussing pelvic inflammation and coxalgia as causes of backache, and also lumbago, about which most of you know much more than I do.

As I said before, I have not attempted a comprehensive survey of the whole of the subject, but I hope that I have said enough to stimulate a discussion.

THE THYROID AND MANGANESE TREATMENT

ITS INFLUENCE ON ABNORMAL BLOOD PRESSURES
(INTERIM REPORT)

BY

HERBERT W. NOTT, M.R.C.S., L.R.C.P.,
LITTLE SUITON, BIPENHEAD

When first practising this therapy (described in the *BRITISH MEDICAL JOURNAL* of March 7th, p. 443) very little notice was taken of its action on blood pressure, and whenever changes occurred they were attributed to coincidence or chance. But as the treatment proceeded, and successful results were being seen in complaints usually recognized as of toxic origin, it appeared likely that some detoxicating process must be taking place in the blood as well as in the tissues generally. It was argued that the changes in blood pressure might be due to the removal of pressor or depressor agents which had, either directly or indirectly, interfered with the automatic balancing apparatus which is understood to govern the circulatory system.

During the past thirteen months careful observations and innumerable blood pressure readings have been made in between 70 and 80 cases, and the impressions recorded in this paper have been culled from the notes on these cases taken in the aggregate. But only 34 are published, as they represent abnormalities of pressure which will be

unquestioned by anyone, whereas the remainder showed digressions which some might accept as being within the normal ambit.

Nor would this paper have appeared just now had it not been for the publication of the late Sir Clifford Allbutt's book *Lithemiasis*, in which Sir Humphry Rolleston drew attention in the *British Medical Journal* of July 11th. In the preface to that book is the following passage:

'It is to be hoped the cause and the secret of the cure of hyperpiesia may be not very long hidden from us, for we are realizing more and more the frequency of the malady. Dr John Parkinson speaks of it as "that very common disease which is responsible for so much suffering and mortality in late middle age and early old age."

After reading this it seemed to me that it was not a matter for two or three to dally with for months, but rather that an early verdict should be given, and that this could only come by as widespread a trial as it was possible to obtain.

This inquiry began in earnest with a case where the systolic blood pressure was 274 mm. of mercury. It was the case of a man, aged 67, who had suffered from a slight puerile seizure two months previously. He entered a nursing home knowing an attempt was to be made to bring his blood pressure to a safer level by a method not requiring change of diet or mode of living, and without taking the medicines he was tired of. Dr George Taylor of Chester was called in consultation, and he confirmed the high reading. Complete analysis proved the absence of organic disease, and he was looked upon as either a case of hyperpiesia of unknown origin, or possibly one of hyperpiesia due to middle-aged disease, from which he had suffered in the past (Case 1).

Rectal injections of 1 pint of the standard solution (1 gram of pure potassium permanganate freshly dissolved in 12 pints of warm water) were ordered to be given twice daily from ten to fifteen minutes after defecation, together with 1 gram of thyroid extract twice daily. The injections were returned from the first, and six days later his systolic blood pressure was found to be 215 mm. of mercury. For the next two weeks he was only given one daily injection, and at the end of that time he returned home with a blood pressure reading of 220, with his breathing relieved, with less cardiac oppression, and a less congested appearance.

In this and many other cases blood pressure readings have been taken daily, weekly, fortnightly, and monthly. Some have shown a tendency to an early rise when treatment has been discontinued, but this has not been our experience with the majority. By far the greater number have responded very rapidly, high blood pressures having been reduced to much safer levels, and low blood pressures raised to more normal levels, in from a week to fourteen days. An improvement in appearance has been seen with an improved sense of well-being, and with some reduction of these signs of the symptoms of such complaints as they find that home duties. Some have been reduced by rectal them. If such gills can so thyroid feeding whilst others, constipation is a thing to be. Again, some who were found to be treated entirely by drugs have responded to treatment help of taking much. and that a few of the mine had been rendered alkaline, and a continued observation has been possible these improved pressures have been returned by in occasional injection or a course of rectal treatment.

It was stated in the first report on this treatment that cathetics of various strengths of potassium permanganate given with plenty of water on waking in the morning, were found useful, but not so satisfactory as were the rectal injections, and in general this has been found to be the case in the treatment of abnormal blood pressures. For several reasons, however the cathetic method of treatment has been followed up and extended, and so far the greatest promise has come from a freely made one containing 1/8 grain of potassium permanganate, combined with 1/2 to 1 grain of thyroid extract. It has been about in this way. It will be remembered that the report (March 7th) contained contributions from two medical men. During the few weeks following its publication letters were received from three times the

number who announced they were joining the investigation with earnestness, and as one after another sent in his opinions and results it was obvious many were finding patients who were unwilling to have the injection treatment. So more attention was given to the cathetic. Various combinations were tried, and are still being tried, but the above formula has been found exceedingly useful in many disorders.

Opinion generally would probably be that thyroid substance would suffer by being exposed to the oxidizing effect of the potassiumate, whereas apparently something is produced which brings about results not always so easily or so quickly obtainable when similar doses of these things are given separately. Here it can be said that this effect appears to have a rapid effect in conditions of neurasthenia accompanied by low blood pressure. In from five to eight days many miserable and depressed individuals of middle age find themselves remarkably improved, and after two weeks' treatment they look and feel rejuvenated, with an intellect and body so invigorated as to be reflected in occupation, business, and sport, and this improvement has been accompanied by a slight rise in blood pressure in some cases. Conversely the picture is not so favourable, but although no high blood pressures have been observed to be reduced some victims of this disorder find they have not to resort so frequently to injections when they take a two weeks' course of these cathetics occasionally.

I have been fortunate in having the whole-hearted help of my assistant Dr I. Hammett, whose unflinching attention to blood pressure readings has made it possible to glean these impressions. Besides Dr Taylor and Dr Hammett I have to thank twenty other doctors who have contributed to these results by taking pressure readings after one or two weeks' treatment, or in supplying information as to the time the malady had been known to exist. The cases noted with an asterisk are those where dual diagnosis and observation has been carried out. This list of cases is presented with the belief that, if it proves nothing, it justifies the recording of some impressions which it is hoped will be found sufficiently interesting to stimulate further inquiry.

IMPRESSIONS

1 That the majority of abnormal blood pressures are due to toxins in the blood, which has been the belief of many for some time, and that most of them can be removed or lessened by this process of detoxication.

2 That probably over 85 per cent. of abnormal pressures can be quickly and safely brought nearer the normal figure for the respective age with a general improvement in health, so long as they are kept under careful observation.

3 That these toxins for the most part are present in the blood by reason of infinitesimal digressions from normal metabolism.

4 That they are by products resulting generally from microbial infections which ought to be eliminated from the body by its detoxicating apparatus—the thyroid and parathyroid system—and have been retained because this system has failed, and in being retained have suffocated, inhibited, or exaggerated the action of this or that member of the endocrine system.

5 That families are to be found who are hereditarily unable to antidote certain poison and depressor agents (Cases 17 and 29).

6 That this most probably determines the tendency to apoplexy in one family and to neurosis in another (Case 29).

7 That it is probable that most of the hereditary diseases will in time be proved by this process of detoxication, or variants of it, to be due to delicate changes in the efficiency of the thyroid gland by reason of its inability to eradicate this or that result of metabolic error. That the mildest inefficiencies of this gland are just as liable to be transmitted as are the gross ones which no one disputes. That enlarged tonsils and adenoids, appendicitis, and gastric ulcer are notable later day results of modern toxins affecting tissues which are hereditarily predisposed to deterioration. That McCarrison's experiments by which he produces congenital goitre in animals go to support this impression. That the number of reports announcing successful results by this treatment in goitre, gout, rheumatoid arthritis, migraine, angina, etc., all point in this direction.

8 That many organic diseases which are considered primary in time be found to be secondary results of irritation of harmful products in the system and of which the sufferer has been unaware.

9 That Dr Gyes' 'specific factor' may be wholly or partly of metabolic origin

10 That it might be advisable to ascertain if any difference occurs in the proportions of successful inoculations in chickens and rats between those that have been and those that have not been detoxicated before the respective viruses were inoculated

11 That considering how frequently chronic mastitis is the forerunner of malignant disease of the breast, some encouragement can be derived from the fact that another successful case can be added to the three described in the first report, where a badly affected breast in a woman aged 50 of cancerous pedigree became normal and healthy after eight weeks' continued treatment

12 That "specific factors" may be concerned in many diseases together with viruses yet to be found

13 That Dr H S Pemberton's recent announcement (BRITISH MEDICAL JOURNAL, July 4th) that he and others have come across a hitherto unrecognized organism in the joints of advanced cases of arthritis points in this direction

14 That detoxication experiments on guinea pigs and rabbits might help to tell us whether susceptibility to disease is in some way due to a waywardness in metabolism. Whether a specific factor of a racial type exists in these animals which permits the human or bovine tuberculous virus to propagate readily

15 That it may be due to minute divergences in metabolism that some diseases are not prone to develop side by side with others. If this is so there may be some significance in the fact that the death rate from cancer amongst the insane is only some 3 per 1,000, whilst the mentally sound are dying from this disease at the rate of 9 per 1,000

16 That many middle aged people are to be found whose domestic unhappiness, shown by changes in temper, taste, or character is directly due to excitations and irritations caused by the retention of harmful by-products of metabolism, of which they are unaware and for which they are not always responsible. That gout is not the only hereditary complaint of the kind which causes abnormalities in blood pressure and an irritability of manner. That numerous combinations of toxins are formed which can so subtly alter character that even life partners drift apart unwittingly—one being driven by the excitement of this combination to an extravagance or an intemperance that jars, whilst the other is reduced by that combination to a state of dependency and alcoholism which disgusts. The timely taking of blood pressures will suggest a course of detoxication, with resulting improvement in both

May I ask the sceptically minded to remember one or two important points before they dismiss this line of treatment as unworthy of trial?

First, let it be remembered that the human toxins have long been known to resemble snake venoms, that snake venoms are of metabolic origin, and, numerous as they are in variety and potency, potassium permanganate is an antidote to all, or nearly all. A significant fact is that all venoms act on the animal body in one of two ways, and can be grouped under two physiological headings. They are either haemotoxic or neurotoxic in their action, death occurring from changes in the blood or from paralysis. Now if the human body is producing toxins resembling snake venoms, is it not possible that we poison ourselves by our venoms affecting the blood and the nervous system? And if potassium permanganate in minute quantities is an antidote to the snake venoms, why not also to the human venoms?

Complete proof would come if it were found possible to lessen the potency of any snake's venom by detoxicating it. Various families of snakes have venoms of various potencies and the bloods of some families are known to be of standard toxicity. If any of these venoms, or toxic bloods, could be found reducible by detoxication in vivo with potassium permanganate or calcium hypochlorite (which, on the authority of Calmette, has an even greater power than potassium permanganate) to the extent of making a member of a family no longer immune to a lethal dose of the venom of its own family, it would be an important contribution to the subject of immunity generally

SUGGESTIONS IN TREATMENT BY INJECTION

In conclusion, I must mention some mistakes that have been made in the technique. In the first place, some are using ordinary commercial crystals of potassium permanganate. The drug must be pure, as it is found in the tablets manufactured by the wholesale druggists. Another mistake is that the injection is given too quickly. It must be given very slowly on a spasm of the bowel

will result and nothing will enter. Most patients retain the fluid better when introduced by funnel and tube. The water ought to be comfortably hot, lukewarm water only irritates the bowel and prevents it being retained. Patients who have been suffering from stasis may not be able to retain more than an ounce or two for the first eight or ten injections. These are just the subjects who will find improvement if they will persevere, and they should be assured that the power of retaining the fluid will come when the bowel has become healthier. The best results are seen when the injection is regularly given in less than half an hour after the bowels have acted. For this reason irregular attendance on the part of a visiting nurse is undesirable, and it is better to choose and instruct some member of the household who can attend to instructions faithfully. The presence of haemorrhoids need not deter treatment, for benefit results, especially so where occasional haemorrhage is occurring.

SUGGESTIONS FOR TREATMENT BY CACHET

Here again the ordinary crystals have been used in place of the pure drug. A reference to the list of adulterants commonly found in these crystals will convince most that harm might come by using them. The cachets must be made with greatest care. The drugs must be pure and fresh, and not a breath of moisture must be present whilst preparing them. Very explicit instructions about this must be given to chemists or no results may be seen, so easily is an eighth of a grain of potassium permanganate reduced by moisture. Not more than sixteen or twenty-four should be ordered at one time, and in the case of the combination cachet, containing thyroid and permanganate, mentioned above, the tablets of these drugs should be powdered separately, and then mixed together.

The Lowering of Pressure in Abnormally High Blood Pressure Cases

In the following list of cases the initials B.P. are to be understood as representing systolic blood pressure readings. Injections mean the standard solution. Thyroid 1 gr. refers to the ordinary tablet of that strength. Cases marked with an asterisk have been under dual observation.

Case 1*—Male aged 68 B.P. 274. Post-hemiplegic condition. Two injections daily for six days B.P. 215. One injection daily for next twelve days B.P. 220. Reading remains between 220 and 240 at the end of twelve months' treatment with one or two injections weekly.

Case 2*—Female aged 38 B.P. 236. Mild symptoms of exophthalmic goitre. Two injections daily for one week, with thyroid extract 1/2 gr. twice daily. Injections continued for two weeks longer but no thyroid given. End of third week B.P. 175 with reduction in the severity of symptoms. (Self administered.)

Case 3*—Female aged 60 B.P. 227. Hyperpiesia of uncertain origin. Two injections daily thyroid extract 1 gr. twice daily for two weeks B.P. 180 with less confusion of thought and improved appearance generally.

Case 4*—Male aged 63 B.P. 226. Hyperpiesia of uncertain origin. Two injections daily for three weeks, thyroid 1 gr. twice daily for two weeks B.P. 191 with reduction in weight. Improved condition maintained for months with one or two injections a week and an occasional dose of thyroid. (Self administered.)

Case 5—Female, aged 69 B.P. 225. Post-hemiplegic condition three years since seizure. Two injections daily for two weeks, thyroid 1 gr. daily. No change observed at the end of two weeks. This case is interesting as being the only one that did not respond to treatment quickly. But with two weeks' treatment with cachets followed by injections for two weeks more B.P. was found to be 170.

Case 6—Female aged 69 B.P. 224. Hyperpiesia of uncertain origin. Two injections daily for one week no thyroid given B.P. 202 with improvement seen in neurotic symptoms.

Case 7*—Female aged 67 B.P. 222. Hyperpiesia of uncertain origin known to have existed for seventeen years. Two injections daily for two weeks thyroid extract 1 gr. daily one injection daily for three weeks. General condition much improved B.P. 165.

Case 8*—Female aged 60 B.P. 215. Hyperpiesia of uncertain origin with slight urinal symptoms. Two injections daily thyroid 2 gr. daily B.P. 186 with relief of symptoms. Noticed middle of third week. (Self administered.)

Case 9*—Female aged 63 B.P. 210. Slight rheumatoid symptoms with thickened knuckles and painful feet. Hyperacidity of urine. Two injections daily for four weeks alkaline powder 1 d.s.p. B.P. 153 suppleness returning in the hands at end of fourth week. (Self administered.)

Case 10*—Female aged 49 B.P. 198. Hyperpiesia of uncertain origin nervousness but nothing definite. Alkaline powder 1 d.s.p. two injections daily 2 gr. thyroid daily for three weeks B.P. 174. Considerable relief to nervy feelings. (Self administered.)

Case 11—Female aged 60 B.P. 198. Very advanced case of myxoedema. Three injections daily for ten days two daily for fourteen days one for many months 2 gr. thyroid daily B.P. 162

in three weeks. Great reduction in weight and disappearance of all symptoms in six weeks. After twenty months' treatment requires one injection every second or third day to keep himself in good health, hands vigorous keep her in better health than by courses of thyroid medication alone.

*Case 12**—Female, aged 55 B P 194 Obesity with dyspnoea and bronchial asthma. Two injections daily for fourteen days with 2 gr thyroid daily. Slight reduction in weight and great improvement in breathing, B P 172.

*Case 13**—Female, aged 53 B P 191 Angina minor long history and quite incapacitated. Two injections daily for three weeks 1 to 5 gr of thyroid extract daily. Complete relief from anginal attacks after four days' treatment continues relieved for seventeen months no return of anginal pain B P 155. Thyroid medication and occasional injections taken.

*Case 14**—Female, aged 39 B P 191 Obesity and mild myxoedematous symptoms. Two injections daily 1 to 4 gr of thyroid extract daily B P 175 end of second week. Disappearance of disagreeable endometritis which had existed for many years and had resisted two cures was noticed on the fifth day of treatment.

*Case 15**—Female, aged 56 B P 193 Bright disease of many years standing. Two injections daily together with the usual treatment for this disease B P 165 in four weeks. Gradual disappearance of albumin and epithelium. All symptoms relieved.

*Case 16**—Male, aged 45 B P 190 Hyperpiesia of unknown origin. Two injections daily for one week one injection daily for six days B P 140 at end of second week, and remained at this figure by taking an injection weekly some months later (Self administered).

*Case 17**—Female, aged 63 B P 190 Hyperpiesia, renal with uricemic symptoms, apoplexy common in family history. Two injections daily for three weeks and one or two injections weekly for sixteen months B P 175 all symptoms improved with reduction in blood urea.

*Case 18**—Male, aged 70 B P 183 Angina minor. Two injections daily for twenty-one days B P 170 relief from anginal symptoms keeps himself comfortable with one injection a week and in occasional course of thyroid medication during the past twelve months (Self administered).

*Case 19**—Female, aged 60 B P 185 Hyperpiesia of unknown origin. Two injections daily for five days B P 150 and keeping at that average after many months by the use of one injection a week. No thyroid given (Self administered).

*Case 20**—Female, aged 51 B P 185 Rheumatoid arthritis recent onset affecting fingers and shoulder. Alkaline powder 10 gr two injections daily for two weeks B P 140 reduction in pain and swelling of joints signs of rheumatoid arthritis almost disappeared at end of ninth week (Self administered).

*Case 21**—Male, aged 56 B P 185 Gouty earache and neuritis. After two injections daily for fourteen days with no thyroid B P 150 and gouty symptoms relieved. Six months later continued relief from gout and B P remains reduced (Self administered).

*Case 22**—Female, aged 47 B P 184 Hyperpiesia of unknown origin. Injections daily for blood eighteen months previously. Two injections daily for one week B P 140 with rejuvenated appearance. No thyroid given (Self administered).

*Case 23**—Female, aged 41 B P 184 Mild symptoms of exophthalmic goitre and nervousness. Two injections daily for ten days with thyroid extract 1/2 gr twice a day B P 149 on tenth day with reduction in anxiety neck less swollen and nervous feelings relieved (Self administered).

*Case 24**—Female, aged 49 B P 174 Mild exophthalmic symptoms with slight rheumatoid condition of hands. Two injections daily for fourteen days B P 142. With continued treatment swollen knuckle joints have disappeared at the end of nine months. Neck quite normal in appearance. Nervousness and tremors disappeared (Self administered).

*Case 25**—Male, aged 57 B P 178 Gouty liver and jaundiced at increasing weight. Two injections daily for seven days with 2 gr thyroid extract daily B P 160 at the end of a week. Has kept up treatment occasionally during the six months which have elapsed as he finds it relieves him and his weight has been reduced by many pounds (Self administered).

*Case 26**—Male, aged 36 B P 172 Acute exophthalmic symptoms of the classic variety existing three weeks but preceded by unaccountable nervousness for some months. Two injections daily for ten days with thyroid extract 1/2 gr twice daily for ten days B P 135. Continued treatment with injections but no thyroid all exophthalmic symptoms disappeared at the end of the seventh week. Five months later is well with one injection weekly (Self administered).

*Case 27**—Female, aged 44 B P 172 Long history of asthmatic attacks with bronchial asthma and inclination to bronchitis. Two injections daily for two weeks with thyroid extract 1 gr twice daily B P 145 at end of third week with relief to asthmatic breathing (Self administered).

*Case 28**—Male, aged 48 B P 170 Hyperpiesia of unknown origin accompanied by unaccountable nervousness which interfered with his business. Two injections daily for fourteen days with no thyroid B P 148 with complete change in his nervous condition. Four weeks later he finds himself able to attend to his business better than he has done for years (Self administered).

The Raising of Pies ups in this usually 1 a Blood Pressure

*Case 29**—Male, aged 49 B P 110 Hypopiesia of uncertain origin symptoms of depression not irritative looks old for his age. Several members of his family with similar low blood pressures.

Two injections daily for three days, one injection for four days B P 124 at the end of a week continued one daily injection for three weeks longer B P 130 Improved appearance in every way, looks younger, has more vigour and more hope in life. No thyroid (Self administered).

*Case 30**—Male, aged 60 B P 115 *Bacillus coli* infection existing for ten years, with recurrent attacks much reduced by periodic rigors and cystitis etc. Injections continued over twelve months having one or two daily, thyroid medication occasionally B P averages around 130, with improved condition no rigors and little or no cystitis.

*Case 31**—Male, aged 52 B P 118 General depression with inability to attend to his business and loss of confidence in himself. Two injections daily, thyroid extract 2 gr daily B P 135 in seven days, with renewed interest in business improved digestion, and increased vigour. After twelve months' treatment with an average of one injection a week notices a less tendency to bronchitic catarrh, which had been treated unsuccessfully by vaccines on many occasions (Self administered).

*Case 32**—Male, aged 60 B P 123 Feeling unaccountably weak and depressed for no apparent reason. Two injections daily for one week with 1 gr of thyroid extract daily one injection daily for second week with continued thyroid medication B P 134 at end of second week feeling renewed interest in his occupation and energy enough to help in his garden (Self administered).

*Case 33**—Male, aged 56 B P 120 Similar case to the above. Treatment as above B P 137 in fourteen days (Self administered).

*Case 34**—Female, aged 67 B P 129 Well developed angina minor which had existed for five years preceded by minor anginal attacks over several years. Two injections daily for three weeks interval of three weeks and injections renewed again for three weeks with 1 gr of thyroid extract daily from the commencement of the treatment B P 140 at end of ninth week anginal symptoms relieved. Fifteen months later found still relieved with B P 190.

Some time having elapsed since the notes were gathered together in preparing this paper observations have now been made in the full complement of 100 cases and in all of them satisfactory changes in pressures have occurred.

CATARRHO-PTOGENIC AND TUBERCULOUS INFECTIONS OF THE LOWER RESPIRATORY TRACT

BEING THE BOLINGBROKE LECTURE DELIVERED BEFORE THE SOUTH WEST LONDON MEDICAL SOCIETY, JUNE 1925

BY

H. BATTY SHAW, M.D., F.R.C.P.,

PHYSICIAN TO THE HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, BROMPTON AND TO UNIVERSITY COLLEGE HOSPITAL

Symptomatic Classification

THE symptoms produced by infection of the respiratory tract may be broadly grouped in accordance with their association with discharges yielded from above the larynx, and those associated with discharges brought from beneath the larynx. For the purposes of this lecture the latter group will prove more than enough, for the infections of the respiratory tract associated with cough and expectoration are not only numerous, but they are of serious moment to the individual infected. The keynote of this lecture is not the rehearsal of those signs and symptoms of the various infections of the subglottic respiratory tract, but a study of the possible influences one sort of infection has upon the effects of another different kind of infection. It is not intended to refer to symbiosis, but rather to the interaction of the end results of such symbiotic functions.

Catarrhal Infections

One of the most familiar infections of the respiratory tract is that group which is characterized by the production of mucoid secretions from the supraglottic portion, and mucoid expectoration from that part below it. Such infections have had to play the part of the neglected Cinderella, and too often the patient can extract from us nothing further than the comment that catarrhal colds need only treating by simple household remedies "they take three days to come, three days to stay, and three days to go away." Sometimes these colds seem to be limited to the supraglottic portion, at others, from the very beginning they appear to attack the lower respiratory tract, at other times they begin above and end below the glottis. About

these catarrhal attacks many discussions have taken place, but to this day we are not sure what it is that gives the organisms responsible for these attacks their chance to operate. We are not even sure that the recurrent attacks to which such subjects are prone are the result of reinfection from without or of revival of infection already resident within. Not all members of the same household develop these catarrhal colds at the same time, some may even escape altogether, so that it is clear that catarrhal colds are not like the acute exanthemata, they differ from the exanthemata also in the fact that, while so many of the latter appear to confer immunity, a catarrhal respiratory infection seems to invite recurrence, the exceptions to this rule seem to confirm this deduction for measles and whooping cough, which are so essentially associated with catarrhal inflammation of the respiratory tract, are known to recur. For want of a better name a special group of catarrhal infections is spoken of as "influenza" and the more the patient suffers from headache and pains generally the more likely is this particular qualification to be accepted. There can be no doubt whatever that the use of the term "influenza" to describe these particular maladies is most useful clinically, though the impression that the disease in question is caused by the influenza bacillus is not justifiable.

These catarrhal infections run a varied course, they may even recur in a short lapse of time, or they may not occur again till a corresponding season ensues—a year or years later. The usual thing is for the catarrhal expectation to be transformed gradually into something quite different.

PYOGENIC INFECTION

At some variable period of time, with the abatement of the more unpleasant symptoms of an attack of catarrh, the expectoration changes in appearance, and a new element announces itself, for what was a glairy, gelatinous material becomes faintly yellow, even deeply yellow, may become greenish, and may even be streaked with blood. If we ask ourselves what has happened to produce this change we really are met with many difficulties. We learn that the poisonous materials produced by the organisms of catarrh can at first only excite the secretion of glairy material, but if they continue to operate the exudation becomes purulent and with the cessation of the formation of pus there is an end to the poisoning and the tissues gradually assume their normal state—the cold is at an end.

It is, however, interesting to speculate whether it may not be that the glairy material is directly due to one set of organisms only, and the pus to quite another set—the so-called pyogenic. After all, easy as it is to realize that an organism can produce excessive mucus, and particularly tenacious mucus as in bronchial asthma, and that another set of organisms can produce pus, it is not so easy to realize that some organisms can function at one moment in one direction, and at another in a totally different one, the most exquisite example of this latter group being the organism that can produce first a red corpuscular exudate, then a fibrinous one and finally a leucocytic one, which last *mirabile dictu* may never appear as purulent expectoration but be quietly got rid of by such powerful digestants as antolytic enzymes.

THE "CARRIER"

It has been the popular belief that each and every attack of respiratory catarrh is due to a reinfection from outside, but so numerous are the deductions that must be made upon such an hypothesis that it is necessary to turn to another possible explanation. It is the common lot of physicians to notice many cases in which, gradually, patients become afflicted with more and more recurrent catarrhs. It is gradually noticed that these attacks do not always come on in the early winter or in the late spring months—a most virulent attack may supervene in the summer, gradually the so-called bronchitis lasts all the year through, and the patient at last joins the army of those suffering from chronic bronchitis. Bronchial asthma may supervene, and also become permanent, or a severe attack of pneumonia, while not destroying life, may render the process of invalidism much more rapid in its development. The converse may be true—a sharp attack of pneumonia or

bronchitis in childhood may be followed by bronchial asthma and repeated or chronic bronchitis and the remarkable fact must be recognized that in some cases attacks of pneumonia recur again and again. Those who have the opportunity of watching the above cases know that the patient concerned may really never be rid of the infection, for in the absence of cough and expectoration bronchi and rules may be present in the lungs for months on end. The doctrine of the "carrier" explains all these cases much more satisfactorily than the doctrine of reinfection from outside.

The Habitat of the "Carrier" Organisms

It is almost certain that quite early in infant life these organisms are present in the respiratory tract, quite probably as mere casual visitors, for it can hardly be imagined that the atmosphere which carries to the adult respiratory tract so many pathogenic organisms would draw the line at the infantile one, such casual visitors need not produce harmful effects, for the child may only harbour such organisms, and even if infected need not necessarily show signs of such infection. It is quite clear that many pathogenic organisms can be harboured on the surfaces of the airways, even including the alveolar epithelium, and it is perfectly clear, too, that these organisms, if picked up by leucocytes, or carried by any agency, may leave such airways and enter the parenchyma of the lungs. Otherwise how could it be explained that abscesses disposed in a necropo form are found round bronchial tubes? It is impossible to say which of these two sets of organisms, those in the airways or those in the parenchyma, is capable of assuming intense pathogenic characters and become the source and origin of a recurrence. The fact remains that the seed is somewhere in the lungs, and something which it is hard to find out and comprehend has given a fillip to these organisms so that from being casual visitors they have been converted into full dressed pathogens.

Functional Capacity of the "Carrier" Organism

The doctrine of the "carrier" organism requires the belief that an organism may reside in the body and yet not produce any pathogenic effects until some fresh circumstance, with which at present we are little familiar, allows such organism to become once more pathogenic. We like to think that by improving the patient's general condition, by life in the country and in the sunlight, we can prevent the organism concerned from exerting its bad effects. It is a peculiarity of the catarrhal organisms that they sometimes exert their most harmful effects in the face of what we call improved hygienic conditions so that the patient may have his worst attack of infective bronchial asthma in the summer in the country, and he may be most free from attacks of asthma while living in London, and we have to fall back upon the view that the continuous "salting" by small returns to pathogenicity on the part of the "carrier" organism is better for the individual than prolonged depression of pathogenicity in the country in the sunlight. We follow Nature's methods by prophylactic vaccination, sometimes with successful results, sometimes with none.

Catarrhal organisms as their name implies, produce exfoliation of the epithelium of the airways and also the discharge of much mucus. It is believed that the same organisms by continued action produce actual suppuration, but it is possible that a quite different set of organisms is really responsible for these pyogenic effects. In either case catarrh generally precedes suppuration. The suppuration may be confined to the surface of the airways, with destruction of tissue, and consequent emphysema and bronchiectasis. If the suppurative organisms reach the parenchyma of the lung, abscesses may form and ultimately cavities develop. If blood vessels are opened then hæmoptysis results. These destructive effects may be described as histolytic ones, and the particular destruction of blood vessel walls could be conveniently spoken of as angiolytic. Angiolytic, however, need not result from the extension of abscess formation to the walls of the adjacent blood vessels, for purpura and allied conditions seem to be due to the local operation of toxic material manufactured at some distance. It is therefore clear that the hæmoptysis met with in infection of the respiratory tract may be due

to suppurative foci, or to angiolytic toxins and such haemoptysis may not be present in the catarrhal cold contracted in January, but be quite serious during the subsequent March and April, without the development of another catarrhal cold. At the same time, haemoptysis may occur only in the early stages of a catarrhal cold, never to occur again during the life of the individual, and, though the haemoptysis may have been severe, neither clinical nor radiological study can discover changes in the lungs. That an angiolytic function may be a feature of an infection in one circumstance, and not in another, is probably the reason why the haemorrhagic types of the acute specific fevers occur, but it is possible that it is the occurrence of another infection with special angiolytic functions which is responsible for haemorrhagic manifestations.

The histolytic functions exercised by organisms met with in catarrho-pyogenic infections may produce other effects—for example, if the abscess of the lung lies under the pleura it may rupture into the pleural cavity, hence an empyema, or pneumothorax, and pyopneumothorax of so-called spontaneous origin, if the abscess ruptures into an adjacent healthy bronchus fresh bronchi and lung parenchyma become exposed to the infection.

To sum up, catarrho-pyogenic infections of the respiratory tract are capable of producing different clinical pictures in different patients, or of producing several clinical pictures in the same patient. These clinical pictures, when occurring in the same individual, need not be equally complete in each person, nor need they preserve any constant sequence. These infections may result in bronchial catarrh, suppurative bronchitis, bronchial asthma, pneumonia, abscess and cavitation of the lungs, haemoptysis, empyema, etc. We need no longer be surprised if an apparently simple attack of bronchitis is accompanied or followed by a smart haemoptysis, nor need we be surprised if an "influenzal cold" is followed by an attack of acute pneumonia, or that an attack of acute pneumonia is followed by what we call clinically bronchiectasis, but which may at post-mortem examination prove to be a condition of putrefactive pneumonia with few or many abscess formations, even with cavity formation, and acute bronchitis.

Such lessons as these are not novel to you, they have, indeed, become a part of your medical beliefs. Successive infections from outside are unnecessary to explain them; the infection is a reinfection from within, but a corollary to this belief is not yet accepted in our profession—namely, that these catarrho-pyogenic organisms may be "carried," and exert their pathogenic results over periods of very many years. We need not feel that too great a demand is made upon our credulity when we are asked to believe that in initial attack of bronchitis and pneumonia in 1910 is the cause of a right-sided pleurisy in 1912, of a so-called influenzal attack and severe haemoptysis in 1922, of chronic bronchitis with fetid expectoration in 1924, with signs only at the base of the left lung, and death almost exactly a year later from intense septicaemia, from diffuse suppuration throughout both lungs, especially in the left one, neither lung revealing, even microscopically, any trace of tuberculosis. The "carrier" theory invites us to believe that the bronchitis and pneumonia of 1910, if themselves not mere expressions of a catarrho-pyogenic infection of many years' date, were at least the first expressions of this group of infections in 1910, the last and fatal ones being operative fourteen years later.

TUBERCULOUS INFECTION OF THE LOWER RESPIRATORY TRACT

If the "carrier" theory can be applied to any infection, it can certainly be applied to the tuberculous one. This infection, like other respiratory ones, probably begins in and about the moment the infant breathes. It is present in a latent form in an extremely large proportion of all adult town dwellers locked up in fibrous tissue, or permeated with lime salt, it is doing no harm—indeed, some think it is doing good, it is mostly deposited in glands, and those about the roots of the lung are the seat of much infection, and so are the minute collections of lymphatic tissue which are found throughout the lung substance. Hitherto it has been considered that the infection by the

tubercle bacillus is a continuous affair, and this view dies hard but it is dying. It is to us the least, in the light of the application of the principle of anaphylaxis to the study of tuberculosis, is likely that the tuberculous infections from outside which really matter are the earliest ones, for the tuberculous infections from outside which subsequently occur are, like the catarrho-pyogenic infections, from outside, not true infections, because they cannot truly infect, as the individual is already infected.

We sometimes see in the young that rare tuberculous infection known as confluent tuberculous pneumonia. It is a true pulmonary tuberculosis. Part or whole of the lung may be involved by an extension of the tuberculosis of the lymphatic glands, the involved lung is a light yellow, somewhat tough tissue—it is nothing more than a congeries of tuberculomata. Another pure tuberculosis of the lung is the diffuse miliary tuberculosis met with in the young subject, which is probably due to the rupture into a blood vessel of a broken-down tuberculous focus, this explains the uniform distribution of the miliary tubercles throughout both lungs. How difficult it is to diagnose at the bedside that either of these conditions is present is well known, because there may be no pulmonary signs in miliary tuberculosis of the lungs, and consolidation of a lung is caused by so many infections.

There is another condition of the lung, officially spoken of in this country as "pulmonary tuberculosis", other nations prefer the use of the term "consumption" or "phthisis pulmonum". The term "pulmonary tuberculosis" should mean a pure tuberculosis of the lung, consumption or phthisis pulmonum is not a pure tuberculosis of the lungs. The physical signs of the condition of so-called pulmonary tuberculosis, it is said, include those of bronchitis, catarrhal or purulent, pneumonia, acute or chronic, pulmonary abscess, cavitation, fibrosis of the lungs, haemoptysis, bronchiectasis, pneumothorax, etc. If tubercle bacilli are found in the expectoration in cases showing these manifestations, then it is said we may with more confidence speak of them all as examples of pulmonary tuberculosis. If tubercle bacilli are not found in the sputum in these cases, we are advised that it would be better for the good of the community especially if these cases are accompanied by debility and wasting still to describe them all as examples of pulmonary tuberculosis.

You see what this entails—you must throw clinical study and pathology to the winds, and say you believe that the tubercle bacillus is a catarrh-producing organism, that it is a pyogenic one, and that it can produce pneumonia and cavitation of the lungs, haemoptysis, empyema, bronchiectasis, empyema, pneumothorax, etc.

A CLINICAL "IMPASSE"

The point of this lecture is to call attention to the impasse, not because it is not familiar, but because I want it to be realized that if we subscribe to the idea that the tubercle bacillus behaves identically with the catarrho-pyogenic organisms we shall inflict a great hardship upon patients, we shall say that they have pulmonary tuberculosis when we have no proof whatever that the tubercle bacillus is responsible for the condition of the lungs. I have known some practitioners say that cases of catarrho-pyogenic infection are so closely allied in symptomatology and signs to pulmonary tuberculosis that they have decided to call all cases of this kind associated with cough, wasting, and debility, examples of pulmonary tuberculosis, although tubercle bacilli have never been demonstrated in the sputum. This is inflicting a great hardship upon those patients who are not tuberculous, and many of you prefer to reserve the term "pulmonary tuberculosis" for those who yield tubercle bacilli in the sputum.

THE APPEAL TO THE SPUTUM

It must be confessed at once that the former criterion by which these two groups of cases are separated has become discredited. There are many practitioners who say that it is useless to base this criterion on sputum examination for tubercle bacilli, for they say that a sputum which is negative to-day may be positive to-morrow, or in three years' time, or it may be positive to-day and for a few days and

then become negative, or it may be continuously alternately positive and negative, or the sputum may be positive continuously for a very long time, and even when the patient feels perfectly well. Many of you are fully cognizant of all the difficulties connected with the questions coming round the nature of pulmonary tuberculosis. You are glad of sympathy, but I am sure you would welcome help as well. You do not want to notify a case as one of pulmonary tuberculosis without being sure, because, if for no other reason, of the calamity such a diagnosis brings to the ordinary household. At the same time, you feel that your patient who yields tubercle bacilli in the sputum should, without any doubt, be removed from near association with young children.

THE CAUSE OF THE CONFUSION

I propose now to discuss shortly matters which have been studied by pathologists and bacteriologists, and upon which, as a clinician, I have no first-hand information. I make use of the knowledge they have gained by exact experimental study to prevent myself from falling into errors and making clinical assumptions for which there is no scientific support. As a clinician I know that catarrho-pyogenic organisms can produce at the bedside and in the post-mortem room certain conditions which are identical with those wrongly alleged to be produced by the tubercle bacillus. I also know that the tubercle bacillus is not always able to be demonstrated in these lesions. I am, therefore, suspicious that there is something wrong in our conceptions of what the tubercle bacillus can do.

Pathologists have found that every adult town-dweller at death shows latent or active tuberculosis, or both, in some part of the body, and in a great many cases in the lung and adjacent areas. I can find no experiments to prove that the tubercle bacillus by inhalation, or by inoculation, can produce catarrh of the bronchi or alveoli, or suppurative bronchitis or bronchiectasis. The tubercle bacillus is not classed as a pyogenic organism; it cannot be made to produce pus by experimental means, though tuberculin can do so.

An organ attacked by tuberculous infection develops tuberculomata, which in favourable cases may involute, but if more tubercle bacilli arrive, more tuberculomata form until a whole organ may be replaced by tuberculomata. The more an affected organ or tissue approaches the surface of the body, or is brought into direct connexion with the outside of the body, the more likely is a suppurative process to be added to the tuberculous one. Tuberculosis of organs deeply buried in the body unconnected with the outside air remains pure tuberculosis; suppuration is exceedingly rare, and, if it occurs, is due to the arrival of pyogenic organisms by way of the blood stream.

In answer to the question, Can tuberculomata *per se* give rise to cavities by the unaided efforts of the tubercle bacillus, and the cells of the tuberculomata and their enzymes? it must be admitted that, though cavities may, and do, form in tuberculomata by a process of liquefaction of the interior of the tuberculomata, such cavities do not the cavities met with in pulmonary tuberculosis. When liquefaction occurs in a tuberculomata, the fluid material may be absorbed and the tuberculomata contracts, and this goes on till at last the tuberculomata becomes healed, or calcified. It is well known, as in the case of a pyous abscess, that this liquefactive process takes place, and this advance is helped by gravity, so that in time an enormous so-called "cold abscess" forms, but its contents are never purulent unless pyogenic organisms are admitted into its interior directly from the outside or by the blood stream. In the same way, cavities cannot arise from a tuberculomata without the help of pyogenic organisms entering the latter from outside, but cavities may be formed in the lungs by pyogenic organisms without the previous existence of the tuberculomata.

It is known that the tubercle bacillus has a great tendency to excite the proliferation of cells new to its site of deposit, and that is why it is spoken of as an organism which is characterized by a proliferative capacity, but at the same time in a sense it is destructive because the cells of which it is formed (derived from fixed tissue cells of several types and even from certain cells which wander from the blood vessels into alveolar spaces, pick up bacteria, carbon,

etc., and then wander back) have assumed a dominating influence, and lead to the complete disappearance of cartilage, elastic tissue, lymphatic vessels, and blood vessels which may have been originally resident at the site in which the tuberculomata has formed, and it is known that the tubercle bacillus, directly or indirectly, first of all causes thrombosis of the blood vessels before it leads to their disappearance. It is clear, therefore, that the tubercle bacillus, so far from exciting haemorrhage (and therefore haemoptysis), is a deterrent.

It is believed by some investigators that the tubercle bacillus can cause exudation of blood cells and plasma from blood vessels, and that therefore the tubercle bacillus on admission to the lungs can cause an exudative pneumonia. The evidence is simply histological—namely, that such pneumonia may be found in the lungs of people who have died having had tubercle bacilli in the sputum, and tuberculomata scattered about the lungs. But when the research is converted into a bacteriological one, then it is found that in the lung tissues there are present not only tubercle bacilli but other organisms which are well known causes of exudative pneumonia, and it is concluded—and rightly—that the pneumonia found in the lungs of people dying with tuberculous disease present in some part of the lung is, with one rare exception (confluent tuberculous pneumonia) already referred to, not caused by the tubercle bacillus.

No one has succeeded experimentally in proving that he can produce in the lungs of an animal the changes met with in the lungs of people who have died of so-called pulmonary tuberculosis by inoculations of pure cultures of the tubercle bacillus. It is very unusual, relatively speaking, for children to die showing the signs and symptoms met with in adults dying of pulmonary tuberculosis. They seem better able to resist the destructive changes in the lungs produced by catarrho-pyogenic organisms than are adults.

It is clear that because Koch discovered that the tubercle bacillus is the cause of tuberculosis we are wrong in assuming that because a patient reveals tubercle bacilli in the sputum his lungs are infected by the tubercle bacillus alone—they may be infected by other organisms as well. Indeed, we are quite sure they are. This is frankly admitted in the late stages of pulmonary tuberculosis, but it is clearly necessary to admit that catarrho-pyogenic organisms may begin to exert their influences upon the lung before or as early as the tubercle bacillus, so that when we are asked what is the latent period for the development of pulmonary tuberculosis we should say it is that period which elapses between the development of simple catarrh or suppuration of the respiratory tract and the development of so-called pulmonary tuberculosis, whether the onset of the catarrho-pyogenic infection was insignificant and unostentatious, or whether the onset was marked by all the turbulent manifestations of an attack of acute pneumonia, influenza, bronchitis, etc., and whether the interval between these events is days, weeks, months or years, few or many.

THE NEED FOR A CHANGE OF NOMINATURE

The present confusion cannot be ended unless it is recognized that the term "pulmonary tuberculosis" is too inclusive. It would be better to use this term to denote the condition of diffuse military tuberculosis of the lungs and confluent tuberculous pneumonia. We should revert to the use of the term "consumption" or "phthisis pulmonum" but we should elaborate this latter term and speak of the condition of the lung as "simple consumption" or "simple phthisis pulmonum" if tubercle bacilli cannot be recovered from the sputum and we should speak of "tuberculo-consumption" or "tuberculo-phthisis pulmonum" when we want to indicate that cases of simple consumption have become complicated by the presence of tubercle bacilli in the sputum.

I will note briefly the features of these different conditions.

1. Pulmonary tuberculosis due to infection by the tubercle bacillus alone—probably an incurable disease difficult to diagnose. It expresses itself as diffuse military tuberculosis or as a consolidation of the lung accompanied by no manifestations of catarrh, suppuration, abscess, and cavity formation, bronchiectasis, haemoptysis, etc. It is

the sort of tuberculosis which should limit itself to a cure when the specific cure for tuberculosis has been found.

2 Simple consumption or simple phthisis pulmonum, called simple by analogy with simple otitis media, simple meningitis as opposed to a condition due wholly to a specific single cause, such as tuberculous otitis media, cerebrospinal meningitis, etc. A condition in which histolysis is produced by extra-pyogenic organisms, the destruction at first may be slight and unrecognizable clinically or radiographically. All that the patient complains of is slight haemoptysis, or even marked haemoptysis, a cough that will not come to an end, as if due to tubercle or chronic catarrhal or suppurative bronchitis, or the patient may complain of several symptoms, and examination may reveal acute or chronic pneumonia, or cavity formation, or bronchiectasis, or putrid bronchitis, with signs especially in one part of the lung, and there may be progressive wasting and debility. In all cases, whether slight or severe, histolysis of some of the lung tissues has taken place. All signs and symptoms may disappear, never to return, or there may be recurrences, or persistent change takes place, and in the latter case extra-pyogenic organisms are "curied" organisms, and may be curied for many years, from the first infection, whatever form it takes. But it is not necessary for the first infection to be accompanied by severe manifestations, or even slight ones. The tubercle bacillus takes no part in encouraging these infections to occur, or in producing any of the signs or symptoms.

3 Tuberculo-consumption, tuberculo-phthisis pulmonum. These terms are somewhat ambiguous, but serve admirably to indicate a condition in which to the above severity or plenitude of symptoms and signs met with in simple consumption there is added the presence of tubercle bacilli in the sputum. These organisms may be present in few numbers, only occasionally, even once only in a long series of sputum examinations, they may be discovered in sputum which is only mucoid in appearance, or which is very purulent, they may be absent in the fluid brought up in haemoptysis, or they may be present at the first attack of haemoptysis, they may be discovered because the practitioner has routine examinations made of all sputa, surprise may be caused by finding the organisms in the sputum in a patient who feels quite well and yields no signs, but "hacks" or coughs up scanty phlegm.

There is no escape from the fact that there is no parallelism between the presence of tubercle bacilli in the sputum on the one hand and symptoms and signs on the other, so that it is not to be wondered at that prognosis is so difficult in these cases, and especially when it is known that cases who have never yielded tubercle bacilli in the sputum which may amount to diaphoresis and ounces a day, even on repeated examination, and even in the presence of signs of excretion, or of pneumonia, or of bronchitis, the symptoms being slight or severe, may eventually in the near or remote future yield tubercle bacilli, few or many, in the sputum.

To imply that such conditions of the lung are wholly of tuberculous origin, whether tubercle bacilli are present in the sputum or not, is to ignore pathological studies, because *post-mortem* examination may show that the lung lesions are not wholly nor in part tuberculous, and experimental study shows that the tubercle bacillus cannot produce all the changes met with in the lungs in these cases.

When tubercle bacilli occur in the sputum they do so in an episode in the progress of a case of simple consumption, this is shown by the fact that the tubercle bacilli are very scanty and are only found on rare occasions, the patient living a long and useful life, the extra-pyogenic organisms responsible for the simple consumption have mobilized the tubercle bacilli by opening up a focus of tuberculosis which has been resident ever since early life. In other forms of tuberculo-consumption the tubercle bacilli are present in increasing numbers, because, a focus of old tuberculosis having been opened, the tubercle bacilli have been aspirated into other districts of the lung, and with the help of extra-pyogenic organisms have produced the common well known type of disease which destroys so many young adults, but takes toll even after a full, or very full span of life.

Reflection will show that this view of the nature of the

changes met with when the lower respiratory tract becomes infected by extra-pyogenic organisms and tubercle bacilli, and of their interactions one upon another, must influence our views not only as to the meaning of the signs and symptoms of such infections, but will give us more certainty in diagnosis and prognosis, more certainty in treatment and, in addition, by showing precisely who are the patients who are responsible for the dissemination of tuberculosis in a community, will reduce the expense to the individual and to the nation of treating without discrimination large numbers of people as if they were suffering from some form of tuberculo-consumption, when in reality they are suffering from an infection which is much more serious than it is thought to be—namely, that brought about by extra-pyogenic organisms.

This view simply requires, on the part of our profession, the examination much more frequently, and infinitely more continuously and thoughtfully, of the sputum for tubercle bacilli.

A reversion to the use of the term "consumption" or "phthisis pulmonum," with the qualifications above suggested, is by no means a reversion in itself. We must still believe that the tubercle bacillus is the cause of tuberculosis, but we need no longer believe that all the changes present in the lungs of a case yielding tubercle bacilli in the sputum are due to the tubercle bacillus. We may believe that cases of simple consumption exist, and are in no way dependent upon early or late tuberculosis of the lungs, but upon extra-pyogenic infection, the proof of this latter position is that critical examination of the lungs in such cases at *post-mortem* inquiry, and the modern radiographic study during life of these cases, show the existence of cases of simple consumption which yield signs and symptoms identical with those of tuberculo-consumption, but differing from the latter condition during life by the absence of tubercle bacilli from the sputum.

THE EFFECTS OF PANCREAS PREPARATIONS BY THE MOUTH UPON CARBOHYDRATE METABOLISM

BY

P. J. CAMWIDGE, M.D. LOND.

Even since the important part taken by the pancreas in carbohydrate metabolism was proved experimentally in 1889, attempts have been made to treat diabetes mellitus by administering the fresh gland, or preparations made from it, by the mouth. On the whole the results have been disappointing, although a few observers have claimed individual successes. The striking and often dramatic effects obtained with insulin diverted attention for a time from other forms of treatment, but the unavoidable disadvantage of a method which necessitates daily injections over long periods, it may be for the remainder of the patient's life, has recently revived interest in this question, again, satisfactory results have been reported by some, while others have met only with failure. Experimental work, rendered possible by the discovery of insulin, has offered an explanation of this divergence of experience and suggested that there are types of cases in which the regular ingestion of pancreas may be of benefit.

The effects of insulin are usually gauged by the fall in the percentage of sugar in the blood which rapidly follows its subcutaneous or intravenous injection, and it has been generally assumed that because no such change occurs when it is administered in other ways it has no influence upon carbohydrate metabolism. This is not necessarily the case, however, for insulin promotes the deposition of glycogen as well as influencing the utilization of sugar by the tissues, possibly the two functions are distinct, so that one may be lost while the other is retained. In order to test this possibility Mr. Howard and I carried out a series of experiments upon rats and guinea-pigs. They were based upon the well known fact that the fall in the sugar content of the blood induced by injecting insulin can be counteracted by injecting adrenaline as long as there is stored glycogen

in the tissues, since adrenalin promotes the formation of sugar from glycogen, whereas insulin has the reverse effect. If, then, insulin given by mouth for example has no influence upon the percentage of sugar in the blood of itself but is still capable of preventing the rise which would otherwise result from an adrenalinic injection it follows that the insulin or at least a part of it having antihyperglycemic properties, has been absorbed into the circulation.

Six rats and nine guinea pigs were first tested for their response to subcutaneous injections of insulin and adrenalin separately and in succession. The average fasting sugar content of the blood in the rats was 0.11 per cent, after the injection of two units of insulin it had fallen to 0.06 per cent by the end of the first hour, while half an hour after 0.25 c cm of adrenalin had been given subcutaneously it had risen to 0.17 per cent. When two units of insulin were injected and followed a quarter of an hour later by 0.25 c cm of adrenalin, an average blood sugar of 0.11 per cent was found in half an hour, one hour and again in an hour and a half. Similar results were obtained with the guinea-pigs, an average fasting blood sugar of 0.09 per cent being reduced to 0.05 per cent by the injection of two units of insulin, and increased to 0.15 per cent by 0.25 c cm of adrenalin. When the two were given in the same doses in succession the rise which should have resulted from the adrenalin did not develop nor did the same fall occur as when the insulin alone had been given, an average level of 0.07 per cent being obtained in one and a half hours, suggesting that the dose was not quite as well balanced as in the rats and that there was a relative excess of insulin. Investigation of the respiratory quotient of these animals showed that an injection of two units of insulin induced an average rise of 6.5 per cent in the rats, and 15.5 per cent in the guinea pigs, while 0.25 c cm of adrenalin given subcutaneously resulted in an increase of 8.3 per cent in the former and 8.8 per cent in the latter. Successive injections of the same dose brought about no change in one rat and one guinea pig, in the remainder there was a rise of 3.2 per cent in the rats and 5.5 per cent in the guinea pigs.

The same animals were then given two units of insulin by the mouth every hour for three hours, and it was found that no alteration in the sugar content of the blood or in the respiratory quotient resulted. On repeating this experiment but injecting 0.25 c cm of adrenalin subcutaneously a quarter of an hour after the last dose, the pronounced rise in the sugar content of the blood when adrenalin had been given alone did not occur, the average for the rats in half an hour working out at 0.12 per cent and in an hour at 0.11 per cent, while in the guinea-pigs 0.09 per cent was found at the half-hour and hour. Two of the rats and one of the guinea-pigs showed a slight rise in the respiratory quotient—2.6 per cent and 1.3 per cent respectively, but both figures are probably within the limits of experimental error. It is therefore evident that when insulin is given by the mouth to rats and guinea-pigs it loses its power of bringing about the characteristic drop in the sugar content of the blood resulting from subcutaneous injection, but is absorbed and retains its property of counteracting the effect of adrenalin.

Further observations upon rats suggested that this property is not due to a chemical neutralization of adrenalin by insulin but is dependent upon their exerting opposing influences on carbohydrate metabolism for when an injection of 0.25 c cm of adrenalin was given subcutaneously, followed immediately by a mixture of the same amount of adrenalin with two units of insulin hourly for three hours by the mouth, the percentage of sugar in the blood was not affected and the respiratory quotient was unaltered in four of the rats and showed an average increase of only 1 per cent in the remaining two. It should be mentioned that preliminary experiments had proved that adrenalin by the mouth has no effect on the blood sugar or on the respiratory quotient.

Rats are peculiarly suitable for feeding experiments as they greedily eat anything, no difficulty was experienced therefore in feeding six rats with large quantities of fresh guinea pig pancreas. Although as much as a whole gland

was taken by each of the animals on one occasion, frequent examinations of their blood at intervals up to four hours showed no fall in the blood sugar which averaged out at 0.12 per cent, compared with the average fasting value of 0.11 per cent. The respiratory quotient was unchanged in five and showed an increase of 2.5 per cent in one, but as there was no rise in the blood sugar this slight increase may have been an experimental error. When these rats were given half a fresh guinea-pig's pancreas by the mouth and 0.25 c cm of adrenalin was injected subcutaneously a quarter of an hour later the percentage of sugar in the blood was not increased and the respiratory quotient was unaltered in four while in two there was an average rise of 2.5 per cent. It is of course, impossible to estimate the insulin content of the pancreas administered in these experiments but it is evident that half a fresh guinea-pig's pancreas neutralized the effect exerted by 0.25 c cm of adrenalin on carbohydrate metabolism more completely than two units of insulin in spite of the fact that by itself it had no more influence upon the sugar content of the blood.

We have carried out a similar series of experiments with a number of commercial preparations of pancreas advertised as being efficacious in the treatment of diabetes employing samples kindly supplied to us by the makers. None of these was found to reduce the sugar content of the blood like insulin when administered orally or by subcutaneous injection, so that evidently, they cannot be used to supplement or replace the entire internal secretion of the pancreas and promote sugar utilization by the tissues. That this is the case, in any rate as regards oral administration is further shown by there being no appreciable change in any instance in the respiratory quotient when they were given to rats in doses advised by the makers for human beings.

Proportions of Fat showing an Increase in the Respiratory Quotient (R.Q.)

	R.Q. Increase	R.Q. Average per cent Increase
Insulin 2 units subcutaneously	6 out of 6	6.5
Adrenalin 0.25 c cm subcutaneously	6	8.3
Insulin and adrenalin subcutaneously	5	3.2
{ Insulin oral 2 units hourly for three hours	0	—
{ Do and adrenalin subcutaneously 0.25 c cm	2	2.6
{ Raw pancreas oral (half guinea pig's pancreas)	1	2.5
{ Do and adrenalin subcutaneously 0.25 c cm	2	2.5
{ Mackenzie Wallis's extract oral 1 g hourly for three hours	0	—
{ Do and adrenalin subcutaneously 0.25 c cm	1	1.3
{ Trypsogen oral 1 tablet hourly for three hours	2	3.3
{ Do and adrenalin subcutaneously 0.25 c cm	2	1.3
{ Trypsogen with gold and arsenic oral 1 tablet for three hours	2	3.1
{ Do and adrenalin subcutaneously 0.25 c cm	7	3.1
{ Insulase oral 5 gr hourly for three hours	2	1.3
{ Do and adrenalin subcutaneously 0.25 c cm	3	1.3
{ Pancreatin (old stock) oral 1 tablet for three hours	1	2.6
{ Do and adrenalin subcutaneously 0.25 c cm	7	11.0
{ Pancreatin (new) oral 1 tablet for three hours	0	—
{ Do and adrenalin subcutaneously 0.25 c cm	7	7.6
{ Foetal pancreas (Harrower) oral	0	—
{ Do and adrenalin subcutaneously 0.25 c cm	6	3.9
{ Pancreas (Harrower) oral	1	1.3
{ Do and adrenalin subcutaneously 0.25 c cm	6	6.1
{ Pancrehepatine oral 1 tablet hourly for three hours	1	7.6
{ Do and adrenalin subcutaneously 0.25 c cm	3	2.2

Several although not all of the preparations appeared to have the power of neutralizing the effect of a subcutaneous injection of adrenalin like insulin or fresh pancreas for when an average human dose was given by the mouth and 0.25 c cm of adrenalin was subsequently injected there was no rise in the respiratory quotient in at least the majority of the animals, and when

an increase occurred it was considerably less than when adenaline had been injected alone (see table). Judged by this criterion, Mackenzie Wallis's preparation, typtogen, especially when prepared without gold and arsenic, and to a less extent insulin and pancreheptine, would seem to contain an antglycogenolytic fraction which is absorbed from the alimentary tract, and, so far as one can tell without means of accurately comparing the dosage, is as active as in raw pancreas. It is probable that the age of the preparation influences its efficiency in this respect, for a sample of pancreatin which had been kept in the laboratory for over a year was found to have no power to neutralize the effect of adenaline, whereas a fresh sample used immediately after its receipt from the maker gave a better result.

If raw pancreas and pancreas preparations taken by the mouth act in human beings as they do in rats it would seem that they cannot be relied upon to replace the internal secretion of the pancreas entirely when it is deficient or absent, for although glycogen storage may be improved by their administration, the utilization of sugar by the tissues is not affected and the progress of the disease will not be materially influenced, when, however, there is merely a relative deficiency of the antglycogenolytic factor due to the abnormal activity of some influence which, like adenaline, prevents glycogen storage, the excessive formation of sugar from glycogen can apparently be controlled and prevented by an adequate dosage of one or other of these substances. In other words, it seems probable on experimental grounds that true pancreatic diabetes, dependent upon organic or functional deficiency of the gland, is not likely to benefit from the treatment to any appreciable extent, but that "non-pancreatic" glycosurias in which the functions of the pancreas are being normally or nearly normally carried out and there is merely a relative deficiency of the internal secretion will probably be improved and may even be cured, if suitable restriction of the diet is practised at the same time, especially in the earlier stages.

My clinical experience with various pancreas preparations, and especially with Mackenzie Wallis's extract and typtogen, tends to confirm these conclusions, for I have found that when their administration is confined to cases where analysis of the blood shows that defective glycogen storage is responsible for the glycosuria the results of adequate and prolonged treatment are satisfactory, but that it is useless, or worse than useless, to waste time on oral treatment where examination of the blood gives decisive evidence of an absolute deficiency of the internal secretion of the pancreas, in such cases insulin subcutaneously is required, either as a temporary expedient while the pancreas is recovering its functions, or permanently when there is organic disease of such extent that an adequate diet cannot be metabolized without. As a rule the non-pancreatic forms of diabetes or glycosuria are met with in the later years of life, and it is interesting to note that most of the cases in which treatment with raw fresh pancreas is reported to have been beneficial have been middle aged or elderly. In some there has been a family history of diabetes or glycosuria—a more common occurrence in the non-pancreatic than in the true pancreatic forms in my experience.

The first case in which diabetes was successfully treated by the oral administration of fresh pancreas was described by Cowles in 1911.¹ The patient, a middle-aged man, is said to have consumed an average of over three fresh pancreases daily, and as a result his appetite improved, his thirst disappeared, a gain in strength and weight occurred, the quantity and specific gravity of the urine fell, and the sugar diminished, although he was never quite sugar-free. The diet was not much restricted, only sugar being forbidden. Eventually the patient discontinued the treatment, the symptoms returned, and he subsequently died after developing a large carbuncle on his neck. *Post mortem* the pancreas was found to be represented by a fibrous cord about one-fourth the size of the normal gland. In this particular instance there was undeniable evidence of serious organic disease of the pancreas, yet large doses of raw pancreas by the mouth were

found to be beneficial. The explanation probably lies in the nature of the disease, which was evidently a chronic interstitial pancreatitis, and this leads me to a brief consideration of the reason why the sugar-utilizing fraction of insulin when given by the mouth does not usually gain entrance to the circulation, like the antglycogenolytic fraction.

The starting point of Banting's work upon insulin was his conviction that the failure of previous experimenters to preserve the antidiabetic hormone in extracts of the pancreas was due to the presence of the associated proteolytic enzymes by which it was destroyed, and his success arose from the adoption of methods of extraction by which their action was avoided. It seems probable, therefore, that the inactivation of insulin and pancreas preparations taken by the mouth is due to the action of trypsin in the intestine, and that this is the case is further suggested by the results of experiments upon healthy rats which Mr. Howard and I have recently performed. We have found that when means are taken to minimize tryptic action in the intestine the effects of insulin given by the mouth, upon both the blood sugar and the respiratory quotient, approximate more nearly to those resulting from the injection of insulin the more completely the action of trypsin is prevented—results which incidentally suggest that it may be possible eventually to overcome the present disadvantages of oral administration and make it applicable to all forms of diabetes. These results also offer an explanation of the success of the raw pancreas treatment in Cowles's case, for when the external secretion of the pancreas is absent or deficient, as analysis of the faeces shows it is if the gland is sclerotic, the inactivation of insulin, or the internal secretion contained in fresh pancreas, will not take place or will be less complete than when a normal amount of trypsin is entering the intestine, consequently the effect upon carbohydrate metabolism will be greater, particularly as regards the sugar-utilizing fraction. It is probable, therefore, that fresh pancreas and active pancreas preparations given by the mouth will improve carbohydrate metabolism in some forms of pancreatic diabetes as well as in the non-pancreatic varieties, under suitable conditions, but as my examinations of the faeces from a very large number of diabetics have shown that an excess of the external secretion of the pancreas is much more commonly met with than a deficiency, more especially in young people and in the earlier stages of the disease, there still remains a very considerable proportion in which no benefit can be expected, at least as the treatment is at present carried out.

THE ULTRA-VIOLET RAYS IN DERMATOLOGICAL PRACTICE

BY

W. F. CASTLE, D.S.C., M.D. CANAB., M.R.C.P. LOND.,

PHYSICIAN TO THE SKIN DEPARTMENTS, QUEEN'S HOSPITAL FOR CHILDREN
AND WEST END HOSPITAL FOR NERVOUS DISEASES

FROM time immemorial the value of sunlight has been recognized in the treatment of disease, but it is only recently that, in this country at any rate, physicians have been able to ensure a constant supply of ultra-violet rays. The mercury vapour and the carbon arc lamps were at once recognized as providing a remedy of high potential value, and were tested against various diseases. Enlarged claims were made for these lamps before a sufficiently long clinical trial had been given them, but they have now been used over a period of some months in the treatment of many different dermatological conditions, and experience has shown in which success may be looked for.

The action of the lamps is both general and local. The general action is that of a powerful stimulant. Young persons respond more readily to this general action than do the old, but patients are few, especially if they live in a town, who do not obtain great benefit. The improve-

ment, physical and mental, in hospital children has to be seen to be believed. The local effect of the ultra-violet rays is in part bactericidal and in part stimulating. The call on the lamp is great but it has been found safe to put children suffering from impetigo contagiosa under the lamps in actual contact with other children without the infection having spread in a single case. The local stimulating effect, such as is required in patches of infiltration and in sluggish ulcers, almost equals that of the x-rays, and as far as is known, is considerably safer. In most cases general treatment has been given, when practicable, in addition to local treatment. It is as well, when commencing a course of general treatment, to find out as a preliminary the "erythema dose," as by this means larger doses can be given, with perfect safety, than would otherwise be the case. Special caution should be used when treating asthmatic patients, as their skin is apparently extremely sensitive to the ultra-violet rays. The erythema dose is measured by stripping a belt on one arm with four circular apertures in it. The arm is then exposed to the light at thirty inches and the apertures are covered over, one after the other, at two minute intervals. By this means the reaction may be tested over a small area of skin after two, four, six, or eight minutes. As a rule, the fainter the patient's skin the smaller is the erythema dose.

Of the lamps available, the mercury vapour and the carbon arc are the most generally useful. Each has its advocates, but in private practice the mercury vapour is the more suitable because of the much shorter exposure required. Locally, the mercury vapour will do all that the carbon arc can do, and do it even better, but it seems probable that the general tonic effect is greater with the carbon arc. Possibly this view may be due to the fact that patients treated by the carbon arc develop, as a rule, considerable pigmentation, and so look very healthy, while with the mercury vapour there is no pigmentation worth mentioning.

In the following paragraphs only those diseases are discussed in which either the mercury vapour or the carbon arc lamp has been used in a long series of cases with success. In many dermatological conditions application of the ultra-violet rays is the reverse of beneficial, and no mention has been made of them. In order to discover, as accurately as possible, the therapeutic power of the rays, all treatments given in hospital were unaccompanied by the use of any external applications such as lotions, ointments, or powders. When the preliminary experiments had been carried out during the summer months were employed, with a view to determining the quickest methods of cure.

Infective or "Septic" Group

Impetigo—Lesions of the face and body can, even in the absence of any local applications, be treated by the ultra-violet rays with the most successful results. Daily exposures, either general or local, quickly prevent the disease from spreading. The crusts drop off and the affected places dry up and heal rapidly. Care should be taken not to stop treatment too soon, as otherwise relapses are frequent. Light treatment combined with local applications affords the quickest and pleasantest form of cure yet devised.

Sycosis—In the early stages of this disease treatment with the mercury vapour lamp will often bring about a rapid cure, while in cases of long standing steady perseverance may avert the necessity of using the method of opilation by x-rays with its attendant dangers. Care must be taken not to give too heavy a dose to begin with and the treatment should be continued for a considerable time after the appearance of the last lesion. As is well known, this affection has a strong tendency to relapse, and treatment should be resumed as soon as any warnings present themselves.

Boils and Furunculosis—Local application of the rays of the mercury vapour lamp to a boil has one of two results. If treated early enough the boil will abort and dry up without ever having come to the suppurative stage. If, however, the boil has already burst, then the rays by their antiseptic action, will cause rapid healing. In furunculosis generalized exposures have proved themselves the most powerful agent in the prevention of any further abscesses.

The exposures will go a long way towards reducing the malice associated with these two conditions.

Carbuncles—What has been said about boils applies to the treatment of carbuncles. Heavy doses of the rays cause healing at a very much more rapid rate than by any other known method. Pain, discharge, and malodorousness after one or two exposures.

Septic Wounds—Exposure to the rays will in many cases cause the discharge to dry up and the wound to heal quicker than by any other method. In fact infections by the pus-forming cocci are, with a very few exceptions, quickly mastered by the mercury vapour lamp.

Multiple Subcutaneous Abscesses of Infants—After incision or rupture of the abscesses, daily exposures should be given during the whole course of the disease. Not only does the lamp assist very materially in causing rapid healing of the lesions, but the general effect in overcoming the toxæmia may actually be the means of saving the child's life. No hesitation need be felt in exposing an infant however young to the rays, so long as small exposures only are given.

Other Conditions

Alopecia Areata—Whether one regards this disease as being due to some micro organism or is of neurotic origin the accepted treatment is the same. Stimulating lotions containing antiseptics will bring about a cure in a large proportion of cases, others will get well spontaneously. But there will always remain some to resist all forms of treatment, and it is in this group that the ultra-violet rays are so useful. Of six cases treated recently in hospital by the lamp only, one alone failed to respond after six weeks' treatment. All these cases were of at least two years' standing. The rays have a most powerful stimulating and antiseptic action than any lotion the scalp can tolerate.

Psoriasis—Much has been written about this treatment for psoriasis, and many extravagant claims have been made, but this much is certain, that in a large series of cases a good proportion rapidly regain a normal skin. This applies to the generally disseminated group and to those cases practically indistinguishable from seborrhoea. Patients with thickened patches of long duration require heavy doses at close range, these can be given with greater safety than the x-rays, so far as my experience goes. To ladies especially this new treatment is an advantage since ointments will ruin any clothes. Treatment of the scalp should be given by lotions and shampoos because the hair cuts out a large quantity of the rays, making it difficult to judge the dosage accurately. If the patient can be treated at the commencement of an attack the chances of obtaining a very rapid cure are extremely good.

Seborrhoea—In any but the most acute forms a few general exposures will effect a cure. Seborrhoea as a rule affects mostly those parts of the trunk not exposed to sun light, and is not found among persons who by reason of working in warm climates wear but few clothes, hence the rationale of the treatment. Infiltrated patches clear up rapidly with a few big doses.

Acne Vulgaris—The results with this disease have been very satisfactory. It is as well to commence with general treatment for the first few exposures and then to give the affected parts a fairly big dose—one large enough to cause a moderately profuse exfoliation. These big doses should be repeated every fourth or fifth treatment as one good exfoliation will accomplish more than weeks of mild treatment.

Lupus and the Tubercles—Considerable experience of the treatment of tuberculous infections by the rays has shown that, while no startling results are to be expected steady improvement takes place in most cases. Treatment must however be continued over a period of some months, three or more exposures being given weekly. Several writers have pointed out the need for caution when treating patients with any active lesions in the chest.

Chilblains—By reproducing summer conditions as nearly as possible a large proportion of cases can be greatly improved. With the onset of cold weather the treatment of those who habitually suffer from this complaint should be begun, and continued intermittently throughout the winter.

ENDOSCOPY OF THE UTERUS

WITH A DESCRIPTION OF A HYSTEROSCOPE*

BY
HAROLD F. SEYMOUR, M.D. LOND., F.R.C.S. EDIN.,
SURGEON TO THE SUSSEX MATERNITY AND WOMEN'S HOSPITAL, BRIGHTON

CHARLES DAVID, in a Paris thesis (1908), described a method of endoscopy of the uterus, in which he employed an instrument consisting of a sheath into which fitted the cystoscope, closed at the far end by a glass crystal and containing near it an incandescient lamp. By enclosing the lamp he hoped he avoided blurring of the visual field due to the bleeding following the introduction of the instrument, but this instrument was never taken up.

Dr. Rubin of New York has described the technique which he has been employing during the last few months, in making endoscopic examinations of the uterine cavity. The hysteroscope which he has used is a modification of the cysto-urethroscope devised by McCarthy, and can only be used combined with gas inflation. He makes his observations without anaesthesia.

Since last May I have been experimenting with simpler means of uterine endoscopy before hearing of Rubin's work, but under general anaesthesia. Patients in England are not so docile as in America, and do not bear so well manipulations which may be decidedly uncomfortable without an anaesthetic. I first began with a tube angled like a uterine sound, to facilitate introduction of the cervix in the usual way. This tube after introduction, was straightened out by the device designed by Messrs Davidson of Great Portland Street, which held it fixed in the straight position. The light was at the proximal or ocular end, reflected into the tube, as in one type of sigmoidoscope, but only fleeting. I obtained some views of the endometrium, but only fleeting ones, as blood oozing out and mucus soon obscured the view. After the examination of a few cases I soon found that it was unnecessary to have an angled tube, as a straight one is easily introduced after the cervix has been dilated up to 10 or 12 mm.

The next problem was to get rid of the obscuration of the view by blood and mucus. Constant irrigation by sterile water or saline did not solve the difficulty, as it was found impossible to get rid of air bubbles, which spoiled the view. I then thought of continuous suction, as used by Dr. Chetlier Jackson for bronchoscopy. I determined to try a hysteroscope made on the bronchoscope principle. The George P. Pilling Company, surgical instrument makers in Philadelphia, have made for me two suitable tubes for uterine work. There are two tubes made of brass, each 28 cm long, one having a bore of 6 mm and the other of 9 mm. The light is at the distal end, and is furnished by a dry battery on the current from the main, after it has been run through a suitable resistance. The distal end, which carries the light, close to the opening, is bevelled at an angle of 45 degrees, and the edges are rounded off so that there is nothing to scratch the endometrium. In the wall of this tube are three channels—one for the light which carries the light, and one on each side for suction, either channel can be used for irrigation if need be. When in use the suction channels are connected by rubber tubing to a bottle with a rubber cork, which is kept a partial vacuum by means of an electric suction apparatus. I have found the Mennell pump satisfactory, it can be used with any voltage, which is a great convenience. The 9 mm tube is intended for general use, the smaller (6 mm) is reserved for the post-climacteric uterus, or for cases where dilatation to over 10 mm is difficult.

For an endoscopic examination the patient is prepared by placing a glycerin tampon against the cervix for two nights to make it easily dilated. I usually slowly dilate up to 12 mm. The hysteroscope is then very gently introduced, a swab on a sponge holder is used as an obturator, and prevents the lamp becoming obscured by blood during the passage through the cervical canal. The suction apparatus should be set going previous to the introduction. When the instrument is passed in almost to the fundus, the swab on its holder can be withdrawn, and only introduced again should the lamp become smeared. With the suction apparatus working briskly, the lamp end of the tube only requires swabbing out three or four times during an examination.

The whole endometrium is then carefully scrutinized by turning the instrument about and by partially withdrawing and reinserting the lighted end. The whole lining of the uterus cannot be seen at once, it has to be examined piecemeal. There is an aluminium handle to the instrument, which is intended to give one direction during use. I find that the more cases one examines the more one can see. The first time a cystoscope is used it is with very little profit to the observer, and so with the hysteroscope one needs practice to become familiar with the appearances of the endometrium in its functional changes during the menstrual cycle and in its alterations from pathological causes.

So far I have examined some fifteen cases, and have been able to see and remove a large fibroid polypus and diagnose a case of fungous endometritis. I derived great help in removing the polypus by being able to trace up the pedicle to its origin on the anterior uterine wall, near the fundus, and snip it through at the right spot by sight, avoiding buttonholing the uterine wall, which can happen when the weight of the polypus has caused a partial inversion of the uterus. The difference between the appearance of the mucous membrane of the uterus during menstrual life and after the menopause is striking, in the latter case the membrane is much paler and smoother. I have also been able to bring into view the os uteri, which is going to prove useful in diagnosing the uterine causes of general bleeding, since it can reveal such lesions as glandular hyperplasia of the endometrium, polypi, and carcinoma. A piece of tissue can easily be removed for microscopic purposes by direct vision. The diagnostic emetage has often been a disappointment to me and, I am sure, to others. The serings removed in this way do not really give the pathologist a fair chance. The instrument and the method of using it here described have the advantage of extreme simplicity. Uterine endoscopy is in its infancy, but from the limited experiences I have had of it I believe that it will be of great use as an aid to diagnosis, and of some therapeutic value also.

THE TREATMENT OF UTERINE FIBROIDS
BY MYOMECTOMYBY
P. L. GIUSEPPI, M.D. LOND., F.R.C.S.,
FELIXSTOWE

It should be a axiom that when surgical intervention is necessary, an innocent tumour should be removed, but the organ which contains it should be left, unless the removal of the tumour alone is a more dangerous operation, or the organ that is left is useless. Myomectomy must from its very nature be a higher ideal than hysterectomy, whether total or partial. Why, therefore, have surgeons and

* Abridged from a paper read before the Brighton and Sussex Medical-Chirurgical Society, December 3rd.

* Presidential address to the Ipswich Clinical Society

gynecologists continued until quite recently to neglect myomectomy?

I trust I shall be able to demonstrate that the mortality of myomectomy is about the same as that of hysterectomy, and that the uterus which is left is a useful organ. The first recorded case is that of Atlee of Philadelphia in 1844. The patient bravely endured the operation which was, of course, performed without an anæsthetic. It lasted nineteen and a half minutes—a very creditable time. One fibroid, weighing nearly 2 lb., was removed, and though peritonitis supervened the patient recovered and was completely cured. Atlee very wisely says that this case goes far in testing the propriety of gisiotomy, as the operation of opening the peritoneal cavity was then called.

After this the history of myomectomy was one of continued opposition until quite recently. In 1898 Alexander of Liverpool pleaded strongly for it, but his opinion was against the consensus of opinion, probably because the mortality was then higher than that of hysterectomy.

Indications and Contraindications

The indications for myomectomy are

1 The fact that the woman is of child-bearing age—that is, up to 40—should indicate the advisability of myomectomy, and is, in fact, its all important indication.

2 All pedunculated and single tumours should be removed and the uterus left.

3 There are cases in which hysterectomy would otherwise be indicated, but in which there are so many adhesions between the womb and other organs that myomectomy is the easier and safer operation. I recently operated on a woman who, five years previously, had had removed, for a tuberculous infection, the left ovary and tube and the right tube. At the operation it was found that there was in the uterus a single fibroid undergoing red degeneration. The womb was bound down by many adhesions. Myomectomy was a comparatively simple operation, hysterectomy would have been most difficult. There are other cases in which the excision of one or more fibroids renders the following hysterectomy a far easier operation.

4 Some patients object to the loss of the uterus. In these cases, even if over age, myomectomy is advisable.

The contraindications are as follows:

1 If the patient is above child-bearing age, all things being equal, hysterectomy is, as a rule, the operation of choice, but when only one or two fibroids are present, if they can be easily and safely removed by myomectomy, then certainly that is the correct operation.

2 It has been taught that only in cases in which there are a few fibroids is myomectomy advisable, but neither the number nor the position of the tumours should deter us from performing myomectomy. The only index for guidance is the ease, rapidity, and safety with which the operation can be performed. If it is possible to shell out the fibroids more easily and quickly than to perform hysterectomy, then myomectomy holds the field. I have removed as many as nineteen tumours from the uterus in one case and completed the operation in twenty-two minutes. That patient is alive and well, and has had one baby.

3 Coexisting disease of the ovaries and tubes is a contraindication to myomectomy.

4 When the patient is blanched from excessive loss of blood, then the operation of choice is that which will take the shortest time to perform, and not as has been taught, hysterectomy. I have shelled out a single fibroid, measuring 6 inches in diameter, from a patient who was blanched from a loss lasting three weeks. The operation lasted eighteen minutes. Hysterectomy would certainly have lasted longer.

5 If malignant, meriod, or septic degenerations are present, then myomectomy is contraindicated.

Myomectomy is indicated during pregnancy under the following conditions: (1) when pre-existing tumours grow rapidly, (2) when acute pain is produced by red degener-

tion, (3) when pressure symptoms make life a burden, (4) when the position of the tumour makes it almost certain that it will produce obstruction during labour.

If any of the above conditions exist operation is advisable. If the fibroids are fairly superficial and not too numerous then myomectomy should be performed and the pregnancy allowed to continue to term. If the tumours are too numerous to be dealt with in this way the pregnancy should be allowed to continue to term, and at that stage Cæsar section, followed by hysterectomy, should be the operation of choice.

The Results of Myomectomy

Unless the results are superior or equal to those of hysterectomy the operation is not an advisable one.

It is important in this connection to consider the following points: (1) the mortality, (2) whether the operation cures the symptoms and whether recurrence of fibroids is common, (3) whether patients are capable of child-bearing after the operation.

1 Bonney has recorded a mortality of 2 per cent for myomectomy with a mortality of 15 to 20 per cent for hysterectomy, but he points out that his mortality has been gradually dwindling. Giles has recorded a mortality of 0.95 per cent as against 0.73 per cent for hysterectomy. The Mayo Clinic, out of 504 myomectomies, had a mortality of 0.8 per cent. Personally it could be expected, I have had very few cases in comparison to these authorities, but up to the present I have had 12 myomectomies with not a single death.

2 If symptoms recur this clearly shows either that small fibroids have been left or that a thickening of the uterine mucosa or uterine polyp is present. Bonney advises that the uterine mucosa should always be opened so as to allow of these conditions being diagnosed and dealt with. It is also important that all fibroids however small should be removed. Giles reports that there had been no recurrence of fibroids in 90 per cent of the cases and that menorrhagia had recurred in 9.3 per cent after operation. The Mayo Clinic reports that out of 504 myomectomies only five later required hysterectomy, a percentage of less than 1. In my series of 12 cases I have, up to the present, had no recurrences and no menorrhagia. I believe this is due to the following of Bonney's advice.

3 The question whether patients become pregnant after the operation is, I think, the important point and clearly shows the superiority of myomectomy to hysterectomy. Since it has been shown that its mortality is practically the same as that of hysterectomy and is after all a preventable mortality, and since it has been shown that the recurrence of menorrhagia is rare then the birth of but one child in a whole series of myomectomies shows the superiority of this operation to hysterectomy for fibroids. Giles has shown that 26 per cent of women who could have children have become pregnant. The Mayo Clinic has reported that out of 504 cases whether married or not and whatever the ages, 24 have had children, 28 children had been born to these women, and 5 more were then pregnant.

In my series of 12 cases, one woman has had one child, one has had two children and one has had three. These six children are all living. One other woman became pregnant, but developed eclampsia and abortion had to be procured. Out of the remaining seven women three have been operated on too recently for any report to be made. One is an unmarried woman and four have remained sterile. I have little doubt that more babies could have been born had the mothers so desired.

The operation is normally one of only moderate difficulty, but at times for various reasons it becomes one of extraordinary difficulty. The abdominal incision should be made vertically to one or other side of the linea alba over the rectus muscle. An incision of 6 to 7 inches is usually sufficient. The rectus is drawn upwards and the uterus exposed in the ordinary way. The Trendelenburg position is often of very great assistance. If possible an anterior incision should be made over the fibroid. Bonney makes a great point of this so as to prevent adhesions between the small intestines and the posterior surface of the uterus,

but it is quite simple to graft a piece of omentum over the incision and thus prevent adhesions. The incision is made through the capsule to the fibroid, which as a rule shells out easily. If any difficulty occurs it is far easier and quicker to carry the incision right through the tumour, the cut surface of which is then gripped with a volsellum and easily shelled out, than to make a long search for the demarcation between the capsule and the fibroid. If there are two or more fibroids, and they are situated close to each other, it is easy to carry incisions down to the other fibroids from the bed of the first, and to shell them out through the same opening. If this is impossible multiple incisions are as easy to deal with as one incision.

In the case of a fibroid with a thick stalk the usual practice has been to excise the stalk as well as the tumour. This, however, leaves a large raw surface. It is preferable to make the incision convex on one side of the stalk so that there should remain a portion of the capsule to stitch over the raw surface. When many fibroids are removed a very shapeless uterus is left, but as involution takes place the most shapeless uterus soon recovers its shape, size, and functions. The uterus from which I removed nineteen fibroids was a shapeless mass, but on examination to day a practically normal sized uterus can be felt, this patient has had one child.

The great danger is haemorrhage. As a rule the bleeding can be controlled by pressure. If this is not sufficient, temporary pressure can be applied to the ovary and uterine arteries with intestinal clamps, care being taken not to apply pressure to the Fallopian tubes by making an opening through the broad ligament, so that one blade of the clamp can be passed through it. The two great secrets of success are (1) to remove all fibroids, however small, only an educated finger can feel a small fibroid through the thickened uterine wall, (2) to obliterate all cavities from which fibroids have been removed, unless this is done there is danger of haemorrhage. Ligatures of silk should be used unless the uterine mucosa has been opened, then crêpe is indicated. The sutures can be passed as mattress sutures or circularly round the cavities so as to obliterate them in layers. Finally, a layer of Lembert sutures should be passed through the peritoneum to cover the last line of sutures. Ochsner's recommendation, that sutures should be tied tight enough to stop haemorrhage, but not so tight as to blanch the tissues, should not be forgotten.

I think Bonney's advice, that in every case the uterine mucosa should be opened and the uterine cavity examined for thickening or polyp, is most important. I feel sure that menorrhagia following myomectomy is often due to simple causes which could easily have been put right at the time of the operation.

The number of fibroids removed from my series of 12 were 19, 17, 13, 11, 8, 6, 6, 1, 1, 1, 1, 1. The time taken at the operation is an important matter. The shorter the time the less the shock, and the more fibroids can be removed. My times have been 22, 30, 25, 28, 20, 30, 21, 25, 28, 18, 39 (when an appendicectomy was also performed), and 25 minutes. The woman from whom 19 fibroids were removed has had one baby, the woman with 13 fibroids has had two children, one with one fibroid has had three children, and the one with 17 fibroids became pregnant but had eclampsia.

I have had in my series one cervical fibroid which weighed over 2 lb, and in one case I removed a large fibroid with red degeneration at the fourth month of pregnancy. The woman was taken with acute abdominal pains. The womb reached nearly to the ensiform cartilage and was very tender. The tumour shelled out very easily, it weighed over 2 lb. The pregnancy was not disturbed and the patient has since had two other children.

I have little doubt that myomectomy is the correct operation not, it is true, for all fibroids, but for a very large number for which hysterectomy is done to day. It seems but reasonable that an operation with so low a mortality which cures the patient's symptoms in so large a proportion of the cases, and which permits of the continuation of child-bearing, especially in these days when children are so badly needed by the nation, should become the operation of choice in the not distant future.

THE TREATMENT OF THE PAROXYSMAL STAGE OF WHOOPING COUGH

BY

A. B. WILLIAMSON, M.A., B.Sc., M.B., CH.B. LOND.,
D.P.H. OXON. AND GLAS.

ASSISTANT COUNTY TUBERCULOSIS OFFICER, SOMERSET; LATE RESIDENT,
EDINBURGH CITY HOSPITAL FOR INFECTIOUS DISEASES

Whooping cough is still one of the chief killing diseases of infancy and early childhood. Hitherto there has been discovered no drug capable of allaying the paroxysms which, especially in infants, so often end in convulsions and death. The following series of observations was carried out at the instance of the late Dr. Claude B. Kei, superintendent of the Edinburgh City Hospital for Infectious Diseases, to find whether the reputation enjoyed by *Drosera rotundifolia* in Scandinavian countries¹ and amongst many general practitioners² of this country, as a specific in the treatment of the paroxysmal stage of whooping cough is justified, by putting the drug to a definite clinical hospital test.

Method

1 Whooping cough cases were selected in pairs, each pair being as similar as possible in respect of (a) stage of disease, (b) severity of spasms, (c) age.

2 Tincture of *Drosera rotundifolia* was given in known strength to one member of the pair, and using the other as a control, either with or without another antispasmodic, both were compared from time to time as regards improvement in the number and severity of the paroxysms.

To facilitate comparison the beds of each pair were placed beside each other in the ward when possible. As a continuous record of the paroxysms and whoops had to be kept day and night, a sheet of paper was placed in a prominent position in the ward, and the sister or nurse by day and the night nurse by night marked up the number or whoops in each paroxysm opposite the name of the patient immediately on termination of the paroxysm.

Drosera rotundifolia was given in the form and dose in which it is usually prescribed—that is, min. ij t.i.d. of a tincture of 1 in 10 proof spirit. The 10 per cent tincture was made up in teaspoonful doses of varying strength, and in four cases the dose was gradually increased by the addition of 1 minim daily to min. xij t.i.d. to test the effect of dosage.

The controls of the majority of the cases were treated with tincture of belladonna, the antispasmodic in which the late Dr. C. B. Kei had the most faith. The dose given was min. ij t.i.d., increasing by 1 minim daily till the pupils were widely dilated. In other cases the controls were not treated with any antispasmodic.

In all 31 pairs of cases were investigated over different periods from February to April, 1925. In 11 of the 31 pairs of cases observations had to be abandoned on account of one or other of the pair dying or being removed to another ward (where control was not practicable) or less than three weeks after commencement of the drug.

Summary of Results

(a) In 16 pairs of cases, using tincture of belladonna as the control, 8 showed greater improvement under tincture of belladonna, 3 under tincture of *Drosera rotundifolia*, and in the remaining 5 pairs of cases no appreciable difference between the two drugs as regards rate of improvement was found.

(b) In 4 pairs of cases, where the control was not treated with any antispasmodic, most rapid improvement was observed in the control of one pair, and in the other 3 pairs of cases no appreciable difference was found.

(c) In 4 cases where tincture of *Drosera rotundifolia* was increased from min. ij to min. xij t.i.d. by 1 minim each day, no difference in the rate of improvement was noticeable. In 2 of these cases the patients developed enteritis after about a week, which stopped in one case a day after the tincture of *Drosera rotundifolia* was stopped, but in the other case enteritis continued after cessation of the drug, and death followed twenty days later. In the latter case there was also a bronchopneumonic element.

Summary and Conclusions

1 Twenty cases of whooping-cough in the puerperal stage were treated with tincture of *Dioscorea rotundifolia* and compared under hospital conditions with controls treated with tincture of belladonna or without any antispasmodic.

2 There is no evidence whatever to show that tincture of *Dioscorea rotundifolia* is a specific in the treatment of the puerperal stage of whooping-cough. On the contrary, its therapeutic action would appear to be negligible.

3 In doses beyond the usual limit of the 10 per cent tincture it is an intestinal irritant and is liable to set up enteritis, which in weak bronchopneumonic cases may prove fatal.

Dioscorea rotundifolia.—Leaves of smoky yield a greenish brown, odorous wet acid in glucose citric acid and probably malic acid and a ferment which converts albumin to peptone. (*National Standard Dispensatory* 1925).

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL

RECTAL ANAESTHESIA

In a memorandum (BRITISH MEDICAL JOURNAL, December 12th, p 1123) Mr. Laine has drawn attention to the advantages of "rectal etherization," and compares it favourably with administration by inhalation. He refers to the report of a case by Mr. Granville Chapman and Mr. McNeillan (BRITISH MEDICAL JOURNAL, September 19th). Judging from these isolated reports it must be inferred that the method is not generally employed, and that the fear of unpleasant sequelae, generated by antiquated writings, still prevails. Dr. Boyd, anaesthetist to the Richmond Hospital, Dublin, drew attention to the many advantages of this form of anaesthesia at the Annual Meeting of the British Medical Association at Portsmouth in 1923.

In my own practice ether by the colon is used almost as a routine for operations about the head and neck. The comfort of a field free from the paraphernalia employed for inhalation anaesthesia cannot be exaggerated. It is the method *par excellence* for excisions of the tongue or jaw and for the removal of goitre or glands in the neck. A fortnight ago I removed a bullet which had been embedded for about four years in the base of the brain. It was a difficult and prolonged operation, but the anaesthesia induced by ether by the colon (Dr. Giffney) was flawless, and added considerably to the comfort of the assistants, the sister, and myself. A tube, fastened in the patient's mouth, carried a gentle stream of oxygen from a cylinder near by. There was very little bleeding during the operation, and there was no vomiting or unpleasant after effects.

The method was suggested in fact back as 1847 by Pirogoff, but owing to misadministration was abandoned and only revived in recent years.

From a wide experience I can strongly recommend the method in suitable cases to those surgeons who have not yet given it a trial.

PREGNANCY COMPLICATED BY NECROTIC
FIBROIDS

On January 23rd, 1925, a woman aged 38½ was admitted under me into the Elizabeth Garrett Anderson Hospital, complaining of abdominal pain. It was chiefly on the right side of the epigastrium, was sometimes acute and had been almost continuous since her last period in August 1924. Examination of the abdomen showed the pregnant uterus (five and a half months) reaching to the level of the umbilicus. Apparently connected with the upper limit of the uterus was a firmer, tender mass filling the epigastrium. A small rounded tumour could also be felt on the anterior surface of the uterus at the level of the anterior superior spine. The patient had previously had three miscarriages, the last ten years ago, and was anxious for a living child.

At the operation a large subperitoneal fibroid, 7½ by 4 inches, attached by a short pedicle to the fundus of the uterus, and a second situated in the mid-line behind at the level of the internal os, about 3½ inches in diameter but not pedunculated, were removed. While with difficulty enucleating the second fibroid, some pus-like fluid escaped and the tumour was seen to be necrotic. The incisions in the uterus were closed by Lembert sutures of catgut. Two other quite small fibroids, apparently not degenerating and not in a position to cause any difficulty, were left in order not to weaken the uterine wall more than necessary. The pathological report states that both fibroids were entirely necrotic and infiltrated with pus cells. Unfortunately no cultures were taken.

The patient made an uneventful recovery and was later safely delivered of a living full-term boy by Caesarean hysterectomy, performed by Miss Chidbren at the same hospital.

PULMONARY TUBERCULOSIS COMMENCING
AT SEVENTY-SEVEN

THE fact that the patient had reached an advanced age when he first developed symptoms of pulmonary tuberculosis is sufficiently uncommon for the following case to be recorded.

A man, aged 80, when first seen on August 12th, 1925, was suffering from advanced pulmonary tuberculosis. The general condition was very poor and the physical signs extended over the whole of the right lung and the upper half of the left. Tubercle bacilli were present in the sputum in considerable numbers. Careful questioning of the relatives elicited the fact that the patient had enjoyed excellent health and remained at work until three years previously, when, at the age of 77, he had developed pleurisy at the right base. Since that time he had suffered from the usual symptoms of pulmonary tuberculosis—cough, wasting, etc.—and had slowly gone downhill.

No family history of tuberculosis could be obtained, and the patient did not appear to have been in close contact with anyone suffering from the disease. He died on September 11th 1925.

Tuberculosis Officer, Hertfordshire

A NOTE ON FROST-BITE

SEVERAL years ago it was my lot to have under my observation about 400 cases of frost-bite among prisoners of war in France. Some of the patients stated that they first observed the condition when engaged in working parties, but as a rule it was first noticed while in the tents or huts, and at times occurred during sleep. Slight burning pain only was experienced but within a short time the affected parts became discoloured and gangrenous. As a rule the lower extremities alone were affected, only in one or two cases were the fingers and ears affected also, and in the latter the lesions were superficial.

The condition varied from mere coldness and paleness in the toe with or without blister formation to massive gangrene of one or both feet and in the comparatively slight cases the lesions were mostly bilateral and symmetrical, and consisted of small superficial gangrenous patches or ulcers on the inner aspect of the terminal phalanx of the great toe. Unilateral distribution was rare. Severe cases did not show this symmetry. One toe only might present the features of dry gangrene but as a rule several toes were thus affected on both feet and in a few cases all the toes were affected.

When the gangrenous condition extended beyond the toe it was of the moist variety, and even when the disease did not extend in continuity beyond the mid metatarsus, isolated portions of gangrene involving all the tissues were present beyond this area in the sole or dorsum and frequently in the heel. In the worst class of cases there was massive gangrene of one or both feet with sickening odour. Pressure was unusual and pain was absent except in a few cases, even then it was not severe or continuous.

In a case of massive gangrene of both feet there was marked oedema of one leg and both knee joints were distended with pus. In a somewhat similar case there was painful effusion in

the left knee joint and left elbow joint, whilst later a huge abscess developed in the left buttock. In two cases pyelitis was present, and in one case pyonephrosis. Inguinal adenitis was rare. Multiple septic wounds were not uncommon, and other complications, such as emphysema, were also noted. Diarrhoea also was not uncommon. In only one case was there gas formation, and that in the knee joint.

Treatment was local and general, and an effort was made to prevent or eliminate sepsis. In cases of superficial gangrenous pytic acid in spirit was applied. Sloughs were slow to separate and ulcers slow to heal. Similar treatment was applied to more advanced cases, and a line of demarcation was slowly formed, but it was not necessary to wait for this, as in all cases observed the limits were obvious.

Amputation of toes was performed by circular incision just proximal to the disease. There was a striking softness of the bone. The tissues were pale and avascular, and there was no bleeding, but in twenty-four hours vasoconstriction gave place to vaso-dilatation, and oozing would occur. Primary suture was not performed, and recourse was had to delayed primary or secondary suture. It was at times necessary to remove all the toes of both feet. Several single and doubtful amputations through the tarsus were performed with unsutured flaps.

Six double amputations in the upper third of the leg were necessary for massive gangrene of both feet. In three cases only was Symes amputation practicable, and in one or two cases there was amputation at the ankle joint by internal lateral flap. In the double amputations the mortality was naturally high. Much amputation was at times the operation of choice, so that the defeat of sepsis, improvement in hygiene, and an abundant supply of nourishing food should mitigate operation at a higher level a hopeful expedient.

Nitrous oxide and oxygen was the anaesthetic, and in no case was a tourniquet used. The tourniquet is always a cumbersome appliance and is seldom necessary. In cases of amputation with a skilled team it is always totally unnecessary.

TEMPORARY BLINDNESS AFTER CONCUSSION

For description by Mr. Geoffrey Anderson (BRITISH MEDICAL JOURNAL, November 28th, p. 1005) of a case of temporary blindness following cerebral concussion reminds me of a similar incident which happened to me personally some years ago when I was a lad of 14.

I was roller skating on a concrete pavement, and tripped up, falling heavily on the left side of my forehead. I was very dazed, but did not lose consciousness, and with assistance was able to walk indoors and sit on a chair. I rapidly recovered, and felt quite well, except for the fact that I was blind, and retained only perception of light. I sat quietly and did not say anything, and consequently was not seen by a medical man. After about half an hour my sight gradually began to return, and was normal fifteen minutes later. There were no after-effects, and the only external lesion was very slight bruising of the forehead.

The explanation suggested—that such symptoms are due to a localized concussion or the occipital lobes due to *contre coup*—seems to me to be a very reasonable one.

at the operation is an interesting case of a very rare condition.
LONDON W. 14. JAMES LANNING, M.D. Lond.

TABES DORSALIS IN SURGICAL PRACTICE

In a day of progressive specialism, the importance of avoiding a narrow outlook demands emphasis. Not only do the boundaries of medicine and surgery insensibly overlap, but conditions essentially medical often simulate purely surgical complaints. A chest lesion is frequently mistaken for a gastric ulcer. Banti's disease simulates gastric ulcer, and pernicious anaemia may simulate carcinoma of the stomach. Three recent cases have impressed me with the frequency with which tabes dorsalis complies surgical diagnosis.

The sole complaint of a man aged 63 was stabbing pain in the end of his stump, a good supracondylar amputation of the left thigh following a street accident some years ago. Two years ago when the patient complained of pain similar to that which he now experiences a diagnosis of painful nerve bulb of the great sciatic was made and he was submitted to operation. The man returned to hospital recently again complaining of a painful stump. The irregularity of his pupils led to a closer examination which revealed the typical Argyll Robertson pupil. The knee jerk was absent in the one intact limb. The marked hypomotility of the ulnar nerve and an anaesthesia on close questioning of rheumatism in the right calf and thigh and of occasional decubiti made the diagnosis of tabes dorsalis clear. This was confirmed by examination of the cerebro-spinal fluid.

The second patient was a woman aged 42 with bilateral valgus. On the right there was an ulcerated area over the aspect of the head of the metatarsal which had been present for a long time, but its secondary to the valgoid deformity. It was a deep indolent ulcer surrounded by thickened skin. Its appearance was somewhat of a pie and it was of a painful. The diagnosis of 'perforating ulcer' was confirmed by the presence of typical tabetic signs.

The third case was a man aged 48 who was sent from Wales with a diagnosis of 'hypertrophy of the prostate'. He complained of difficulty of micturition for the past six months, and recent examinations showed that the prostate was undoubtedly enlarged. However, a rubber catheter was readily passed into the bladder. The fact together with certain signs elicited by routine examination of the central nervous system suggested that the disease was degenerative rather than mechanical and the laboratory findings of the cerebro-spinal fluid were conclusive. Wassermann reaction strongly positive, globulin in excess, lymphocytes 60 per cent, metachromatic zone gold colloid curve. The case was clearly one of tabetic dysuria.

For permission to make use of these three highly interesting cases, I am indebted to Mr. Thelwall Thomas and to Mr. Frank Jerns of the honorary staff of the Royal Infirmary. Such cases indicate the necessity for all those who wield the knife being able to say, in the words of an eminent living surgeon, 'I am a physician doomed to the practice of surgery.'

P. WATSON JONES,
Surgical Registrar Royal Infirmary, Llanelli.

TUBERCULOUS DISEASE OF THE TONSIL

The following case seems of sufficient interest to be placed on record.

A man aged 48 consulted me on October 5th 1925 complaining of severe pain on swallowing. I was informed that in May 1924, he had suffered from haemoptysis and that the sputum was found to contain tubercle bacilli. A few weeks later (when undergoing sanatorium treatment) he developed a painful larynx which lasted for four months but eventually cleared up, leaving no symptoms referable to the throat. At the present time his pulmonary condition is satisfactory, physical signs and the X-rays indicate that the disease is confined to the right upper lobe. There is nothing to suggest activity, no loss of weight, and no tubercle bacilli are present in the sputum.

Between October 5th and 20th the dysphagia grew progressively worse and any hot or spiced food caused exquisite pain, all the pain being felt in the laryngeal region on the left side. During this time the larynx and tonsils appeared healthy, the latter being quite small. Very little could be seen in the larynx to account for the pain, the only abnormality being slight injection of the epiglottis and scarring of the left ventricular band. There was no ulceration or swelling.

On October 30th the larynx appeared normal but there was a small white ulcerated area about the size of a lentil on the lower pole of the left tonsil. This area was exquisitely tender to the slightest touch with a probe causing severe pain. Since then several other small ulcerated areas varying in size from a pin's head to a lentil have appeared, some of these areas have coalesced and spread on to the left posterior pillar of the fauces.

The case is undoubtedly one of tuberculosis of the tonsil, and is interesting owing to the presence of very severe pain before the appearance of any local disease.

PALE BABIES AND DEEP PERAMBULATORS

The modern baby is apt to be pallid, even though it may be plump and muscular. The modern perambulator is deep and dark, so that a small infant lying at the bottom of it, covered with a waterproof apron of some dark material and shaded by the hood, is out of reach of any sunshine or daylight.

We found our infant daughter at the age of 2 months pasty-faced and white, though thriving well enough as regards weight and general nutrition. Her diet of Grade 4 milk suited her admirably, and she took 5½ ounces (diluted with 1½ ounces of water) every three hours.

There seemed no reason for changing her diet. So we tried the effect of bringing her up to the surface, placing a light wooden tray in the pram at such a height that with her mattresses the baby lay not more than four inches below the sides of the pram. The hood and waterproof apron are only drawn up when it is actually raining.

In three days the child's complexion changed from a pasty white to fresh pink, and so it has remained.

This note may be of value in directing attention to the drawbacks of a deep pram, and the advantages of raising the infant occupant up into the light of day.

CLINICAL AND SCIENTIFIC PROCEEDINGS

SWANSEA DIVISION

A clinical meeting of the Swansea Division of the British Medical Association was held at the Swansea Hospital on December 3rd, under the presidency of Dr URBAN MARKS, chairman of the Division. The meeting was well attended, and a number of interesting cases were shown.

Dr KINGSTON KNIGHT showed a case of diabetic gangrene, which had eroded and entirely removed the hard palate of a middle-aged woman. With the aid of an obturator made by Mr S. J. St. Heher Tweney, dental surgeon to the hospital, the patient was now able to speak quite well again. Dr H. R. TIGHE showed a case of frigus of the scalp successfully treated by x-rays. Dr DANIEL E. EVANS read notes on a case of renal dwarfism. The characteristic stunting of growth with bone deformities was associated with much thirst and polyuria, while the urine showed a slight cloud of albumin. After an operation for acute mastoid disease uraemic symptoms supervened, and the boy died. At the necropsy the kidneys were found to be small, and to show well marked interstitial fibrosis.

Dr A. F. SLADDEN, pathologist to the hospital, gave a short account of the colloidal gold test as used in examination of the cerebro spinal fluid. He outlined the colour changes which might occur in suspensions of colloidal gold, and showed how the precipitation of gold produced by some solutions of abnormal cerebro spinal fluids was probably due to globulin. In opposition to this precipitating power of globulin there appeared to be some protective power associated with other protein constituents of the cerebro spinal fluid. In order, therefore, that the precipitation might occur, globulin must be present in abnormal amounts and not be opposed by a sufficiency of "protective" protein. The interplay of these two factors determined the character of the colour changes when a series of dilutions of cerebro spinal fluid were added to colloidal gold suspensions. Curves could usually be constructed to show graphically the type of colour change which had been produced in any experiment, and Dr Sladden demonstrated certain typical curves from which diagnostic conclusions could be drawn in association with other factors. Cerebro spinal fluid removed from patients without any organic neurological disturbance gave invariably negative results, so that the presence of a definite curve was significant, while, in addition, the form of the curve provided still further information. A practical demonstration of the test was then given on a sample of cerebro spinal fluid taken from a case of acute myelitis.

Reports of Societies.

THE TEACHING OF PRACTICAL MIDWIFERY AND GYNAECOLOGY

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland, Sir WILLIAM SLYKE, in the chair, the president, Dr D. G. MADILL, gave an address on the teaching of practical midwifery and gynaecology.

Dr Madill expressed his strong conviction that the present method of teaching obstetrics and gynaecology to medical students might well be improved. The lack of adequate practical knowledge had been brought to his notice, particularly within the last six months, by several incidents, of which he mentioned two. In the first, a practitioner of about one year's standing had failed to diagnose a marginal placenta praevia, the second was a fatal case in which a condition of contracted pelvis had been similarly overlooked. Dr Madill thought that the student did not learn much from obstetrical lectures, and though a considerable amount of knowledge had to be obtained from textbooks, yet he was strongly of the opinion that much practical midwifery could be taught by means of models. Whilst holding the position of Assistant Master in the Rotunda Hospital he had started a class in operative midwifery, and had devised a most effective apparatus in the form of an artificial uterus which would hold an artificial foetus. The artificial uterus was made of jam-gee tissue, with a lining of jaconet, well greased with vaseline, a rubber band served as an os. An artificial foetus was similarly prepared, and it was astonishing how

much practical information could be given to the students in the way of palpating normal and abnormal positions of the child and internal and bipolar versions, in learning extraction of the breech, application of forceps, and in practising all the manipulations of operative midwifery except the surgical kinds, such as pubiotomy and Caesarean section. A linseed poultice served admirably as a substitute for the placenta. After a course of this instruction the students acquired great interest in the subject and familiarized themselves with all forms of obstetrical diagnosis. The internal and external measurements of the pelvis could be taught, and though a contracted pelvis could not be used practically, yet the course of instruction had so stimulated the students' enthusiasm that they quickly acquired in the wards the power to make a accurate diagnosis by palpation, to detect an unfixed head, and, what was more important, to ascertain by pressure on the fundus whether the head would be likely to enter the pelvic brim. In Dr Madill's opinion there were too few skilled obstetricians at present in the Free State. While travelling in Northern Ireland he had noticed the rapidity with which in the small towns fully equipped cottage hospitals were springing up, a competent obstetrician was associated with each one, so that difficult maternity cases could be treated without involving much travel for the patients. With regard to gynaecology, Dr Madill had found that by means of an apparatus consisting of a rough pelvic diaphragm of sheet india-rubber, and a plastic model of the uterus, the student could be taught to recognize retroversion and retroflexion, as well as to replace such a uterus and to insert a pessary. While he did not object to the pessary so far as the student was concerned, he condemned it wholeheartedly in the case of the specialist. The practitioner who had recently finished his medical training might use a pessary in two conditions only: in a patient who, owing to disease of the heart, lungs, or to old age, was unable to stand operative treatment, and, in early pregnancy with retroversion. A third case might possibly be added—namely, a patient who refused operative treatment in spite of persuasion. Apart from these three exceptions a pessary should not be used. Dr Madill concluded by expressing his hope that the future medical government of the Free State, whatever form it might assume, would direct attention to the teaching of practical midwifery and gynaecology. He believed that with the aid of the great maternity hospitals in Dublin and the mass of material available for use, a great improvement in practical teaching could be effected.

Sir WILLIAM SLYKE, after pointing out that no student could ever be certain that when he was qualified he would not be called upon to do midwifery, referred to the improvements in obstetrical teaching in London and elsewhere. He looked upon clinical examinations as the most important thing in teaching. There was a great difference between giving a certificate and holding an examination, and he did not see why the medical officers in hospitals should not be examiners also.

Dr GIBSON FITZGIBSON thought that many students aimed at doing only as much work as would enable them to enter for their examinations. The correction of this fault should not be the duty of the clinical teachers but of those who devised the curriculum. If a student learnt how to recognize that the normal physiological process of labour was being followed he would be able to manage safely 90 per cent of the cases he would meet in practice. It was not necessary for the general practitioner to diagnose accurately an abnormality, even if he did diagnose it he was probably not competent to deal with it successfully by operative means. It was sufficient to recognize that the case was out of his province, just as in the case of other special branches of medicine and surgery. Attendance on a course of theoretical lectures in midwifery was useful, but these lectures should be chiefly devoted to explaining the normal physiology of pregnancy and labour just as normal anatomy and physiology were taught prior to clinical medicine and surgery. With regard to gynaecology it should be enough for the student to be acquainted with the characters of the normal female pelvis, to be able to make a vaginal examination, and to recognize any departure from the normal. The great fault in the present teaching of obstetrics and

gynaecology did not lie in the course laid down in the curriculum, but arose from the absence of any defined period of time being set apart during which the student should devote himself to these subjects and be freed from other courses.

Dr L. CASSIDY believed that the tendency had always been to regard obstetrics as the least and last part of a student's medical education, though, since obstetrics and gynaecology concerned the reproduction of the community, it was really the most important part. If normal midwifery were properly taught that should be quite sufficient, as 60 to 70 per cent of cases were normal. At the Coombe Hospital an afternoon class was held three times a week, when the students were given an opportunity of feeling the normal uterus. After this, when they encountered an abnormal case they would be able to recognize it and send the patient to a specialist for treatment. Students were not given enough time for midwifery and gynaecology. He agreed that they should live in hospital for at least three months.

Dr BERTHIL SOLOMONS said that the last occasion on which this subject had been discussed by the Section was in 1910, when two changes were proposed to improve the teaching. One was that the student must attend theoretical lectures before taking his practical course in midwifery, the other was a practical examination at the end. Since then there had been but few changes. There was great need for thoroughly equipped laboratories in charge of efficient teachers, but there must be close co-operation between the laboratory and the ward. The final examination in midwifery was the first encountered by the student, and he must be taught to visualize a patient when asked theoretical questions. Dr Solomon then referred to the report on the teaching of midwifery and gynaecology furnished by Sir William Smyly at the request of the General Medical Council. Ante-natal clinics were absolutely necessary in this age of prevention, and post-natal clinics were relatively necessary. In teaching midwifery the student must have a knowledge of both the physiological and the pathological teaching with the manikin was extremely useful. When an assistant at the Rotunda Dr Solomon used to hold a course in operative obstetrics, using injected stillborn infants for demonstration. This method was also employed in Vienna. For twelve years he had taught gynaecology to large classes at Mercer's Hospital, and had no difficulty—with the assistance of a patient, plasticine, and a pelvis—in getting students to understand the position of the uterus and adnexa. He believed that theoretical lectures, clearly given, were a necessary adjunct to the textbook.

Dr J. S. QUINN regarded instruction in normal midwifery as the most essential part of teaching, and felt that too much instruction in abnormal midwifery tended to make students unduly interfering. Every student should be compelled to reside in a maternity hospital for three months during part of his final year. He thought students should not attend theoretical lectures until they had done the practical work in a maternity hospital. They would thus learn a great deal more from the theoretical lectures, as it was impossible to visualize terms like "post-partum haemorrhage" unless one had seen such a haemorrhage occur.

Dr A. H. DAVIDSON said that students had very little chance of seeing or examining the babies in hospital. He thought they should be encouraged to study the babies and learn how to look after them. Dr B. D. CRICHTON, when he first graduated, had never put a pair of forceps on to a living subject, and he felt that if students were now allowed to do this, instead of just applying them to dummies it would be a great advantage. Further advances would be made if the teaching could become more practical. Dr W. D. Q. KERR suggested that there should be a post-graduate course in midwifery in a lying-in hospital in the last post-graduate year, and that unless this course was taken out general practitioners should not be allowed to do midwifery at all. An examination at the end of this post-graduate course should be compulsory. Dr J. J. ROWLETT feared that there was a danger of the Dublin school losing its pre-eminence in midwifery because it was too conservative in the teaching of this subject.

THE VIRUS OF VACCINIA

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland on November 27th, with the President, Dr J. W. BIGGIE, in the chair, Dr E. C. HORGAN read a paper on some recent work on the vaccinia virus, and gave a demonstration of a method of standardization.

Dr Horgan referred to the recent report by the Medical Research Council on the viruses of vaccinia and variola, and said that although the former was now generally regarded as being one of the ultra-microscopic filter-passing viruses, many workers had failed to demonstrate this property. Enough attention had not been paid in the past to the adsorption of the virus by the material (porcelain, kaolin, etc.) of which the filter was composed. In this respect he recalled the success of French workers who were able to filter vaccinia virus through the extremely small pores of collodion membrane. M. H. Gordon's method of standardizing calf lymph was described in detail, and a rabbit was shown on the skin of which three lymphs had been titrated. No. 1 lymph was received from the Lister Institute, which was potent 1 in 10,000, No. 2 a French lymph (1 in 1,000), and No. 3 a lymph from Sandymount (1 in 100). These results Dr Horgan compared with Gordon's findings, and pointed out the considerable discrepancies. He suggested that the variations in potency were due rather to variations in the virulence of the different strains used by the many workers than to any differences in the standards of manufacture. Vaccinia virus behaved very differently towards various antiseptics and disinfectants (Gordon). Thus carbolic acid was inactive even in a 1 in 20 dilution, while mercuric chloride was active in 1 in 10,000, and potassium permanganate in 1 in 100,000. In two experiments Dr Horgan had confirmed this extraordinary sterilizing action of potassium permanganate. The recent work of Ledingham on the reaction of the skin to vaccinia virus was described as a welcome break away from the old tradition that there was a specific affinity between epidermal tissues and virus. All evidence now supported the view that the primary lesion was in the reticulo-endothelial system, while the well-known changes in the Malpighian layer of the skin were secondary. The serum of an animal immunized against the virus contained several demonstrable antibodies—namely, a complement fixation anti-vaccinia (anti-vaccin) and lysin. The lysin appeared to act without its serum titre was a valuable guide to the progress of immunity in an animal. The modern conception of immunity against vaccinia or variola viruses brought it into line with the common bacterial infections such as typhoid or cholera, and would undoubtedly be of great value in the treatment of diseases caused by these and other filter-passing viruses.

The President said that the organism connected with vaccination differed from those connected with some other diseases in its very small size. The point raised by Dr Horgan regarding the relation of antiseptics to this virus was very interesting. Such conceptions as cellular immunity were accepted without sufficient proof. He referred to the development of antisera, and the possibility of producing one which would be useful in connection with small-pox. The dilution method would, he thought, soon become the method by which the potency of the virus would be standardized.

Thrice Malignant Tumours

Sir WILLIAM WHIFLER and Dr J. LAIT showed a specimen of sarcoma of the tongue in a woman aged 56.

Sir WILLIAM WHIFLER said that it first sight the condition resembled an ulcerating carcinoma, but as the patient was a woman and there was no adherence of the growth to the floor of the mouth the diagnosis became uncertain. The tongue could be moved freely, and protruded to the normal range. There was slight enlargement of the submaxillary gland, probably due to pressure on the duct. There was a history of injury from a dental plate about eight months before and owing to an extension of the sore caused thereby the artificial teeth were dispensed with. The provisional diagnosis was that the

condition was inflammatory, a small portion was sent for examination, and the report was returned that it might be a sarcoma, but the surface was very septic and the whole much degenerated. A second section of the margin of the growth was negative. The ulcerated portion was destroyed by fulguration but within a few days the growth reappeared. Excision of half the tongue was performed. The entire specimen was sent for examination and reported upon as sarcoma. The Wissemann test was negative. Sarcoma of the tongue was admittedly rare, and was most often found during childhood. The growth in this case appeared to be very characteristic, a small tumour suddenly began to grow rapidly, disintegrated very quickly, and was seen first in an ulcerated and sloughing condition. Like others described, it was quite soft, and not well differentiated from the surrounding tissue. The ulcer had a funnel or crater like shape, at the bottom of which lay necrotic tissue.

Dr J LAY said that the tumour was composed of many large, oval nucleated spindle cells, and some round cells, intimately mixed with a variable amount of fibrous tissue. The presence of many mitotic figures was evidence of its activity. There were also present numerous capillaries composed of a single row of endothelial cells and quite distinct from the vascular granulation tissue at the edge of the tumour.

The President said that the condition was one of great rarity. From the photographs and the specimen itself, there seemed to be no doubt at all that the tumour was a sarcoma, in some of the photographs there was evidence of the rapid growth of malignancy, and he thought that the prognosis could not be regarded as favourable.

Dr W D O'KELLY suggested that the tumour might be an endothelioma, and not a sarcoma. The cells seemed to him to resemble endothelial cells, and he did not think the tumour was quite cellular enough for sarcoma. Dr T T O'NEILL agreed that it might be an endothelioma.

Professor J T WIGHAM thought the tumour was a genuine sarcoma, not an endothelioma. The vascularity was mostly in the surrounding granulation tissue and not in the tumour. There was no supporting tissue in the vessel walls, and if it was a malignant angioma he thought that there would be much better formed vessels in the tumour itself. The cells had comparatively small bodies and large nuclei, and did not resemble endothelium. Metastasis of sarcoma in the glands was comparatively rare. Enlarged glands in the neighbourhood of a sarcoma were probably due to sepsis rather than to the growth itself.

Sir WILLIAM WHEELER, replying, said that the patient was going downhill, and he did not regard the prognosis as good. He agreed that the enlargement of the glands was probably due to the inflammatory condition surrounding the sarcoma.

Dr A R PARSONS and Professor J T WIGHAM showed a specimen of an intrathoracic tumour in a boy aged 12. On admission to hospital last April the boy had very distinct stridor on the slightest exertion, and the glands on both sides of his neck were enlarged. There was no enlargement of the spleen or of the thorax. A large area of dullness was found on the left side of the thorax, and harsh breath sounds. No pleural effusion was present, but there was some distension of the superficial veins on the right side. After four x-ray exposures the boy nearly died. After three days of radium treatment improvement began, the patient could sleep better and breathe more easily. He left hospital three months later greatly improved, though still pyrexial. In September he was again admitted to hospital and had more radium treatment, but in November he contracted chicken-pox, from which he died.

Professor J T WIGHAM said that a solid mass had spread downwards from the thyroid over and beside the heart, and a similar mass, apparently a matted mass of enlarged glands, extended up the left side of the neck. It appeared to be formed of a number of hard white round bodies embedded in a fibrous substance. The enlarged glands were almost entirely composed of hard fibrous tissue, with a few vessels and very few nuclei. In some parts the cells were more numerous, and included lymph cells with a few plasma cells, or cells resembling lymph cells but with larger bodies. The vessels in these areas had thick hyaline walls. The

cervical glands resembled those in the thorax, and were matted together by dense fibrous tissue. There was no evidence of necrosis, and the glands were not tuberculous. The question arose whether this was an example of the action of radium on a tumour of the type of lymphosarcoma or a case of chronic inflammation somewhat resembling Hodgkin's disease. There was no sign of glandular enlargement anywhere else, nor was the spleen enlarged.

The President said that though the clinical history suggested sarcoma, yet the patient had a certain amount of pyrexia, no involvement of the spleen, and only a limited number of glands were involved, this made him think that the case was one of Hodgkin's disease. Professor Wigham had not been concerned with the tumour in its original condition, but after it had been subjected to radium and x-rays.

Dr W C STURGEON said that after radium treatment the glands seemed to shrink considerably, but from the beginning the case was hopeless, except that radium seemed to relieve the symptoms. He had spread the radium in small quantities all over the chest, from the front to the back, and had given the maximum amount without injuring the skin. He thought that the boy would have died during the night when the first radium treatment was given if he had not had it. He did not regard this as a case of Hodgkin's disease, the glands became smaller and softer, but did not disappear as in Hodgkin's disease.

Dr W D O'KELLY suggested that it might be a thymic tumour which had possibly started in some of the bronchial glands. The boy might have died, conceivably before enlargement of the spleen had occurred. He thought it probable that this was a case of Hodgkin's disease.

Sir WILLIAM WHEELER said that in young people who developed carcinoma (for instance, in cancer of the stomach in children) there was often pyrexia, and this was supposed to be due to a rapid division of cells and the production of toxins, which were absorbed. This might have happened here. He had obtained good results from x-ray treatment in Hodgkin's disease. It was thought that all mediastinal tumours were malignant, but some were fibromata and lipomata, and could be removed successfully by operation.

Dr V M SARGENT had recently had two cases of intrathoracic sarcoma treated by x-rays. In one treated by the Erlangen method the tumour had diminished to about half the original size, but the patient had died suddenly two months later. The other patient had been treated by x-rays and had also improved, but immediately after the treatment there was an increase in the dyspnoea, apparently due to an inflammatory reaction, it subsided in a couple of days. This sometimes occurred also in cases of goitre after x-ray treatment. He thought that x-ray treatment was much more beneficial in these cases than the Erlangen treatment.

Professors MOORHEAD and WIGHAM exhibited a specimen of a rare intracranial tumour. A man, aged 42, was admitted to hospital complaining of vomiting and headache which had persisted for three months, and presented the typical signs of meningitis—rigidity of the back of the neck and Kernig's and Brudzinski's signs. There was nystagmus but no optic neuritis, and the knee-jerks were absent. A lumbar puncture revealed extreme tension, but apart from the absence of sugar and a slight increase in the cell content the fluid was normal. After a month in hospital the patient died without further symptoms having shown themselves. A lumbar puncture was performed every second day for the relief of the headache. The brain on removal appeared quite normal, except for a slight filmy thickening of the pia mater here and there. After hardening a complete brain examination showed nothing more to the naked eye, but sections showed that the slight thickening was due to a tumour formation of endothelial type. This was spread out over almost the entire surface of the brain in a layer not so thick as tissue paper which penetrated the brain along the blood vessels forming perivascular sheaths. In many places the cells on the surface of the brain were only one row in depth, but within the sulci endotheliomatous clumps of cells were found. As no primary tumour was found in the brain it seemed almost certain that this growth must be regarded as a primary spreading endothelioma almost unique in type. The cells resembled those

further distance from the face, the facial eruption forming only part of a generalized eczematization. It was difficult to say whether there was any underlying condition common to all these cases, or whether it only required some irritation to set up the eczema. Much depended on the state of nutrition of the particular child. Asthma and recurrent bronchitis were apt to occur in children who, in earlier years, had had facial eczema. A return he obtained to a questionnaire suggested that in the facial cases one was dealing with a specialized form of

which was not met with in the other. Most of the scalp cases were infective, and to them the term "seborrhoea" was usually applied. Past histories of cases of flexural pruritus showed that a large proportion had facial eczema in infancy, it was also said that cyclical vomiting and laryngeal fever occurred later in these facial eczema cases. There seemed in these to be some underlying diathesis which persisted throughout life. In the children who were suffering from specific food proteins, they must have got them from their mother's milk, and most observers found in these children a reaction to proteins. A large number of infants with facial eczema showed evidences of overfeeding, and the flushed hyperaemic face might determine the child rubbing and then scratching it. With regard to treatment the main necessity was to put a stop to the friction, partly by methods of restraint. *Chango of temperature he regarded as the most potent cause of itching, therefore the child should be in a room or rooms in which the temperature was equable.* This was the best antipruritic, and a reduction in the amount of food taken was indicated. Bromide was occasionally useful, but he seldom used drugs in these cases.

Dr H. C. CAMERON opened for the Children's Section, and stated a number of questions which arose in the mind on this subject. Was death from eczema a death from generalized eczema? It seemed to be in some cases, and in some it seemed that the infants had suffered from the extensive use of ointments, and especially from branding the skin. He was inclined to divide the cases under discussion into two: (1) the generalized eczema of the very thin, young babies, and (2) the eczema of the fat, older babies, the latter having especially eczema of the cheeks. If the fat babies were rendered thin, thus at the same time improved their eczema, and if the thin babies were well fed their eczema also improved. There were three conditions in young infants in which sudden inexplicable death occurred: eczema, spasmophilia, and status lymphaticus, the latter being, he considered, the *post-mortem* finding in all children who had a very high lymph content in their body. Frequently in records of death from status lymphaticus it was stated that the child had suffered from eczema. The connecting link in these three conditions he considered to be the poikilo-osmotic tendency in these children. He entered into a detailed description of the different types of child, and said in many there was a low grade of acetonaemia. He was always advocating breast-feeding, yet in a number of cases weaning was quite justifiable, at least alternating breast-feeding with feeds from the bottle, for he had seen this have a remarkable effect in improving the eczematous condition, and the substitution of vegetable soups was equally successful.

Dr H. G. ANDERSON began with the epigram "Eczema covers a multitude of skins." He said that if the area affected was protected from rubbing it subsided, and if that were continued it disappeared never to return. Cases which persisted after 2 years of age became altered in character and distribution, and might persist until adult life. Most adult cases he believed, started in childhood. Eczema was a cutaneous inflammation of the skin characterized by a scious exudation into the whole thickness of the skin, coming to the surface as minute weeping follicles. He believed it was independent of any digestive disturbance or any food idiosyncrasy. External irritants he regarded as the sole factor in causation. Though he had seen many thousands of cases of infantile eczema, he had never known a sudden death from it, he agreed with Dr. Whitfield that cases so attributed were due to chill.

Professor F. LANGEVIN thought there was great need for a scientific and careful subdivision of conditions now classed under the one term "eczema." He thought the

eczematous type of skin might be hereditary, though it might be acquired, in some infants both factors were associated. In eczema of the nates, he thought an irritant in urine or faeces was insurmountable, and in all cases the aim should be to keep the skin free from those irritants. Some were associated with a protein idiosyncrasy.

Dr J. M. H. MACLEOD said it was no longer the idea that there was a definite disease which could be labelled eczema, as far as could be seen it was a type of reaction, and thus could be better studied in the infant because it was there uncomplicated by other factors—such as mental ones—as in the case of the adult. His conclusion, based on a very large field of observation, was that eczema in infants was a local condition, locally produced by irritation and scratching. When the skin became thus hypersensitive it showed a reactive response to all kinds of minor irritations which otherwise would have made no impression.

Dr G. H. LANCASHIRE (Manchester) expressed his agreement with the views of Dr. Adamson and Dr. MacLeod, and spoke of the value of coal tar in allaying irritation. He also referred to the harmful part played by the application of evaporating—therefore cold producing—lotions.

Dr. HARRY DAVIS said protection and the adoption of antipruritic measures were the sheet-anchor for these cases. He thought the sugar content of the blood was a factor which would repay investigation.

Dr. MURRAY BRIGH (Liverpool) thought some cases of sudden death in eczematous children resulted from the attempt to cure the eczema too soon. There should be a good nurse, and she should apply and keep applied olive oil to the whole body.

The discussion was continued by Mr. FRANK COFF, Dr. S. E. DORE, and others, and the President spoke of the importance of ascertaining whether a skin eruption was due to an external cause before making a complicated investigation as to possible internal influences. Dr. GRAY and Dr. CAMERON briefly replied, and at the close the operators and speakers were thanked by resolution.

PSYCHIATRY

THE Section of Psychiatry of the Royal Society of Medicine held a clinical meeting at Bethlem Royal Hospital on December 8th. Dr. FOTHERGILL prepared an interesting exhibition of specimens of brains and slides from cases of encephalitis lethargica. Stereo-microphotographs of spinal chistics were also shown. These illustrated a new method of obtaining a stereoscopic view at high magnification, devised by von Welckheim and Christeller of Berlin. They were sent by Dr. R. M. Clark of Whittingham Mental Hospital. Dr. PONTIER PHILIPS showed a case which had developed symptoms suggesting dementia praecox following encephalitis lethargica. He also showed a case of Koisakoff's syndrome. Four cases of general paresis which had been treated with malarin in 1923 were shown by Dr. HARVEY for Dr. WORSTER-DROUGHT. Dr. BEATON showed a case of adolescent psychosis, and he raised the question as to whether such a case should be called dementia praecox. An interesting discussion of these cases followed in which many of the members present participated.

PLASTIC SURGERY

At a meeting of the Nottingham Medical Club and Society, under the presidency of Mr. H. BEN TAYLOR, Mr. H. D. GILLIES (London) gave an address on the present scope of plastic surgery, illustrated by numerous lantern slides and the demonstration of cases. Mr. Gillies described the development of the tubed pedicle graft, and also demonstrated his method for the restoration of the nose. He added an account of the treatment of cleft palate, stating that the usual operations were of little value so far as the production of normal phonation was concerned, and they also produced deformity of the jaws and distortion of the "bite." He illustrated the method he advocated—separation of the hard and soft palates and suture of the soft palate only, the gap in the hard palate being closed by a denture. He claimed that this produced a mobile soft palate in its proper relation to the pharyngeal walls, and that the bite remained normal.

Reviews.

MANIPULATIVE SURGERY

At this juncture, when a celebrated dramatist has bared the terrors of newspaper publicity in order to lecture the medical profession on its shortcomings, and when Parliament is likely to be asked to recognize osteopaths and bone-setters, the appearance of Mr. TIMBRELL FISHER's book on *Manipulative Surgery*¹ is most timely. In it he not only reminds the profession of its shortcomings in neglecting the treatment of those cases which enhance the reputation of irregular practitioners, but he also places in its hands the knowledge which, rightly used, should deprive such persons of many of their opportunities.

Mr. Fisher writes of bone-setters in no hostile or envious spirit, for he recognizes that from the elder Hutton's days onward they have done work which was to a great extent neglected by surgeons, despite the good advice given long ago by Sir James Paget and the lessons placed before them by Hutton's pupil, Wharton Hood. For while experience alone can confer the ability to decide with confidence when a stiff joint should be moved and only practice can perfect methods, yet that experience and that practice will be much sooner and better acquired by those who have studied this book than by others who have not.

Mr. Fisher considers that the preaching of the importance of rest by Hutton and by H. O. Thomas, while amply justified when applied to tuberculous lesions, has done harm in a large number of cases. He does not, we think, give enough credit to the English orthopaedic surgeons of the last century who were certainly not afraid to break down adhesions in and around joints, with or without previous tenotomy.

The author classifies the cases which bone-setters cure under four heads—namely, cases with adhesions, functional hysterical cases, unreduced dislocations or subluxations, and a miscellaneous group which includes cases of adhesions in the soft parts not in the immediate neighbourhood of a joint. Injuries of the knee are fully dealt with. The internal derangement known as displaced semilunar cartilage is very properly characterized by Mr. Fisher as a fracture-dislocation, for it is the displacement of part of the cartilage that causes symptoms and its replacement by manipulation that constitutes the bone-setter's "cure." Mr. Fisher is an authority on treatment of this injury by open operation, therefore he is not likely to be accused of wide-and-see methods when he describes and advocates the manipulative method in certain cases. The good results which often follow manipulation for stiff joint after toxic or chronic arthritis are illustrated by histories of cases. All the joints of the extremities and of the spine are discussed in turn, but none of them with such fullness as the knee, which may perhaps be taken as typical. The author agrees with Jones and Lovett in the opinion that it has not been definitely established that subluxation of the sacro-iliac joint is a cause of chronic backache, the dictum of some American orthopaedic surgeons to the contrary notwithstanding.

We wish Mr. Fisher had told us more about the sometimes violent but often successful manipulations practised by bone-setters in cases of lumbago and chronic backache. He refers to *Hexenschuss*, or witch's shot, this sudden onset of lumbago without known cause was so called by the Germans because it was supposed to be the effect of black magic, an enemy having made an image of the sufferer and with appropriate rites having shot a missile into its lumbar region at that particular instant. A vivid description of such an incantation and shooting is to be found in "The Leech of Folkestone," in the *Ingleby Legends* which although it is in prose, has all the fantastic charm and humour characteristic of Baiham.

It would probably be too much to say that Mr. Fisher would in no case use a splint or plaster-of-Paris, but throughout this book he does not advise their use, or even mention the knee-ice, which has been found useful by others.

This book should be a very useful guide, not only to

specialists, but also to general practitioners who, by appointing to early treatment, may prevent cases from becoming opprobrious to the reputation of the profession. But the irregular practitioner need not fear that any publication will deprive him of his livelihood as long as hospitals exist and even superior persons believe that no good can come out of the Nazareth of scientific medicine and surgery.

MODERN HEALTH BOOKS

THE Modern Health Books,² edited by Professor D. FRASER HARRIS, is a series of little volumes designed to give the latest expert opinions in a popular form. In the first volume, *The House of Health*, Sir JOHN ROBERTSON describes the essential requirements of a really wholesome dwelling, especially of the smaller type. He holds that environment is almost as important as the dwelling, and therefore is grateful to the pioneers who instigated the Housing and Town Planning Act of 1909. Although it is often difficult to get people to move from their one roomed dwellings into accommodation that is larger and more convenient and decent, the author finds that education is gradually making them demand conditions more consonant with healthy existence. The Act of 1909 made it possible to prevent congestion of dwellings, to allocate areas for factories, to provide open spaces and to arrange roads conveniently. After dealing with questions of site, soil, conformation of the land, orientation of the dwelling, and cleanliness of the atmosphere, Sir John Robertson comes to the cost of the dwelling. At present the price is rather more than twice as large as in 1914. The pulson type of house costs about £500. The more important craftsmen—the bricklayer, the carpenter, and the joiner—are just the men who are most difficult to obtain. The ideal in town planning is the construction of narrow residential roads, with wide separation of the dwellings, the roads being designed in such a way as to avoid through traffic. In rural areas the type of cottage need not differ much from that in towns, though owing to the larger families more houses with over one or two bedrooms are necessary. Sir John Robertson favours the construction of bathrooms in rural cottages, but as in many places a water supply is not laid on to the cottage the time is perhaps not ripe for the additional expense involved. Even if all cottages in places where there is no public water supply were provided with wells and pumps, it may be doubted whether the cottager will be willing to undergo the labour involved in filling a fixed bath. Notwithstanding the voluminous discussion which has taken place recently with regard to "pulson" or "non pulson" houses, Sir John Robertson favours the pulson type. But he describes suitable houses of both types and has a strong objection to the construction of flats for the working classes. The book contains several diagrams and illustrations, amongst the latter a view of two Cotswold cottages. The typical Cotswold house is, according to the author, perhaps the most elegant of all the types of dwelling-house in this country.

Of the second volume of the series, *Nursing in the Home* it is not easy to speak quite so favourably as of Sir John Robertson's book on housing. Dr. STELLA CHURCHILL, his perhaps, attempted too much. It is difficult to see why the person untrained in medicine should require a description of the symptoms of all sorts of infectious and other diseases, including encephalitis lethargica and cerebro spinal meningitis, nor is it edifying for the anxious but ignorant parent of a child with appendicitis to find that the misgivings of the author pro and con operation have drawn from the editor a note which might be interpreted to mean that, as the appendix is a vestigial organ, and "our culture tube," we had all better have it out as a precautionary measure. Oracular statements of this kind are only suitable for old-fashioned popular dictionaries of medicine, with the help of which the head of the house either delayed sending for the doctor until too late, or else threw the whole family into a state of anxiety over a cold in the head. Dr. Churchill

illuminating section by Dr. Hurst on the radiology of the alimentary canal.

A tracing of the human voluntary tetanus would be more instructive when taken on a slower moving surface than that on page 180, and the average number of "events" per second in that tracing is not 6 to 8 but 10 to 12. Further, this figure (10) ought to be correlated somehow with the much higher one (50) obtained by the galvanometer.

Professor Cathart is responsible for the third section that on chemical physiology, which is very good. The quantitative methods are clearly described and the chemical examination of the faeces, which is so often left to the pathological chemist, is given here in adequate detail. The properties of colloids, and particularly their behaviour with the Beilfeld filter, might have been treated. It is so simple to show the junior student what the "reducing power of the tissues" means by marking him up a little fresh liver press-juice with some dilute soluble Prussian blue, and see the colour vanish, that some exercise of the kind might have been included.

At the beginning of the book there are two pages in small print crowded with a more useful collection of arithmetical data than we ever remember to have seen brought together before in any other treatise on physiology.

There are three separate indexes. The paper, the printing and the binding are most attractive.

PERITONITIS

Peritonitis, by Dr. J. GARLAND SHERRILL, is one of a series of surgical monographs, published by Messrs. Appleton, under the editorial supervision of a committee of medical men. The volume before us contains ten chapters of which the first deals with the anatomy, development, histology and physiology of the condition. When discussing in another chapter the reaction of the peritoneum to foreign bodies, the author has collected a number of strange and interesting cases. Among the embryos issuing he gives left hi surgeons, in addition to swabs, forceps, scissors, drainage tubes, catheters, and glass magnets, are two finger rings and one pair of spectacles! The list is a strange oversight, and we may wonder whether it led to the fashion among surgeons of wearing horn-rimmed spectacles firmly clasped round the ears. Equally curious are the number and variety of articles which Nature has succeeded in discarding by her own unaided efforts.

In the chapter on examination of the abdomen the auxiliary methods of pneumoperitoneum and cholecystography for cases in which the diagnosis by physical means is obscure are fully described. The author reviews the old forms of treatment only to discard them. He inclines to the opinion that the proper course is to lessen the number of cases in which drainage is employed. Washing out of the peritoneal cavity is discussed, but is not recommended. Dr. Sherrill believes firmly in the protective forces of the peritoneum, and thinks that the peritoneal cavity is best cleaned by means of the suction pump. He bans purgation and opiates until the diagnosis is clear. In the post-operative stage he acknowledges a leaning towards gastric lavage and rectal instillation of normal saline. He thinks that in intraperitoneal haemorrhage the use of auto-transfusion will be likely to produce a higher mortality than will the operation alone as usually performed. Auto-transfusion finds most of its adherents in Germany and good results are claimed for it. In the hands of others it has been found to be not without its dangers, of which the greatest is apparently the contamination by bacteria of the blood taken from the abdomen. The method of intraperitoneal transfusion with citrated blood is also described.

Of the many illustrations, some are not worthy of the text which presents a clear well reasoned and conservative account of a subject about many aspects of which there is abundant room for differences of opinion.

EVOLUTION AS AN AID TO RELIGION

Concerning Evolution contains the Dwight H. Terry Lectures delivered by Professor J. ARTHUR THOMSON of Aberdeen at Yale University in 1924. The object of the lectures was to show that evolutionist description is not inconsistent with religious interpretation, and that evolutionary science may illuminate the religious outlook. In the first lecture, on the 'Making of worlds,' the professor suggests that creation has been well thought out "that in the beginning was mind" and that "God made things make themselves." The first picture is of a nebula and the elusive spirit thereof, the irreducibles being electrons and protons. But behind the physical there was the psychical though in integrative impulse a world was fashioned suitable for life. Science gives us a cosmogony, which seems to be congruent with a philosophical or religious cosmology. In the second lecture 'Origin of evolution' is defined as a continuous natural process of racial change in a definite direction whereby distinctively new individualities arise and flourish alongside of or in place of the originitive stock. In the evolutionist picture there is a progressive integration and a strong suggestion of purposiveness, it is, therefore in harmony with the religious vision. In this lecture Professor Thomson summarizes the Darwinian theory.

In the third lecture, on the evolution of man, Professor Thomson tilts at 'materialism' as an attempt to give a false simplicity to the ways of organisms by trying to fit them into frameworks of chemistry and physics without recognizing the distinctiveness of "life" and "mind." Similarly 'biologism' attempts to give a false simplicity to the life of man by trying to fit it into the framework of zoology. Hence an obtusive physiology insinuates that the ductless glands altogether determine the personality. To Professor Thomson there cannot be any rational anti-thesis between scientific description and religious interpretation. There may be clashing as to details and forms of expression, but not in principle. Evolution is, on the whole integrative, and makes for the emergence of mind and personality, it is an ascent, not a descent, that lies behind us. Thus does Professor Thomson escape from the disheartening theological doctrine of the Fall.

The book is very readable and well illustrated and the lectures carry out the object of the founder, which was not the promotion of scientific investigation, but the building on the truths of science into the structure of a broadened and purified religion.

THE CLIMATES OF THE UNITED STATES

PROFESSOR DECOUREY WARD has produced a very complete treatise on climatology with especial reference to *The Climates of the United States*. Although the book is designed primarily for teachers and students of geography the author has had constantly in mind the advantage of making it interesting also to medical men, foresters, agriculturists and the general public.

After mentioning each meteorological records in the United States upon which the climatology of that country is based, Professor Ward summarizes the major climatic controls—namely, latitude, land and water, mountain barriers, altitude, prevailing winds, ocean currents, and storms. The configuration of the United States renders it possible to divide the country into climatic provinces. First the Eastern province from the Rocky Mountains to the Atlantic which is subdivided into the Eastern province proper, the Gulf province bordering the Gulf of Mexico and the Plains province which is included between the generalized line of the 2,000 foot contour and the generalised red line of the main Rocky Mountain divide. The second main province is between the Rocky Mountain divide and the Sierra Nevada Cascade divide, to this is given the name

² *Concerning Evolution*. By J. Arthur Thomson, M.A., LL.D., Professor of Natural History in the University of Aberdeen, New Haven, Yale University, Press, London, Humphrey, Milford, Oxford University Press, 1925. (Med. E. o. pp. x + 245, 25 figures, 11s. 6d. net.)
³ *The Climates of the United States*. By Robert DeCourcy Ward, Professor of Climatology in Harvard University, Boston, U.S.A. Ginn and Co. 1925. (Dem. E. o. pp. xii + 518, 144 figures, 4 dollars.)

of the Plateau province. The third is the Pacific province, a narrow coastal strip west of the Sierra Nevada-Cascades Professor Ward then discusses the paths and influence of cyclones and anticyclones. In the chapter on temperature he points out that the rapid coast from Southern Florida or Northern Maine is, considering the distance, the steepest temperature gradient in the world. As a result the products of tropical and of polar lands are separated by less distance than is the case anywhere else. The contrast in climates was an immense force in stimulating the early economic development of the Thirteen Colonies. Several chapters in Professor Ward's book are devoted to rainfall and humidity and their effects on agriculture and health. In the chapter on "Climate and Health" it is accepted that the older view of the predominant influence of climate has been replaced by the conviction that good hygiene is more important than climate alone. The effect of a change of climate is due more than to actual change in atmosphere, occupation, and food more than to actual change in atmospheric conditions. Perfect climates do not exist, and in climatology it is not necessary to look for the one ideal climate, but rather to select one out of six or seven localities any one of which will do all that climate can do to restore health. In such selection not only must the climate have a maximum of undesirable features, the particular case and a minimum of accommodation, the locality must be provided with suitable food, and expert medical attendance. In fact, Professor Ward is of opinion that when Hippocrates wrote, "In chronic diseases it is advisable to go to another country," he had in mind, not merely the benefits of a change of climate, but also the benefits of a change in the environment—social, mental, and physical. This chapter on climate and health, in which reference is made to the book on climatology written in collaboration by Dr F. Parkes Weber and Dr Guy Hinsdale of America, contains many sound observations. Thus, in writing of the southern winter resorts Professor Ward says "It is, perhaps, fortunate for the future race that so insignificant a part of the population as a whole can afford to bask in the warm sunshine of luxurious southern winter resorts." Altogether the book is most interesting, although its very completeness has led to a good deal of repetition. As the principles underlying the climate in the United States are equally applicable elsewhere, the book should appeal to English as well as American readers.

NOTES ON BOOKS

To the many other Scandinavian Acts there has now been added the *Acta Tuberculosis Scandinavica*, on the editorial committee of which all four Scandinavian countries are represented. It is published in Copenhagen by Messrs Levin and Munksgaard, and four numbers forming a volume are to cost 25s. The first number, which has just appeared, contains in addition to a few abstracts and reviews two long signed articles. One is by Professor H. C. Jacobsen of Stockholm on the cauterization of apical adhesions, and the importance of bronchography in the treatment of the other, in tuberculosis by an artificial pneumothorax. We have French is by Dr Knud Faber, who reports his own experience and those of other Danish physicians in the treatment of pulmonary tuberculosis with sanocrysin. We have referred to Dr Faber's work in the *Epitome* for May 9th, 1925 (para 470), and our issue of July 11th (p 74). In dealing with the reports from various Danish sanatoriums, Dr Faber states in his present article that good results have been obtained in 107 out of 231 cases. He admits that the time is not yet ripe for passing judgement on sanocrysin, but claims that "it is evident that we have here an agent, the action of which is specific and which, in a certain number of cases effects rapid and marked improvement the like of which cannot be expected from any other method."

It is not often that a book is written on hospital routine for the guidance of house officers, and Dr GLOVER H. COPHER'S *Methods in Surgery* will be a gift to them. It is an epitome of the procedure followed in certain Washington hospitals and the University dispensary there. In the hospitals of medical schools, where routine teaching is a continuous process by members of the staff, who evolve their own methods, this

book will not be of so much use as in smaller non-teaching hospitals where the changing house officers come from different schools. It gives a way to meet hints on history taking, which are likely to arise, and useful hints on history taking, and the recording of physical examinations. There is a good deal of information for registrars as to forms and charts used in general and special cases, and their filing and indexing. House officers would be helped in the management of their chapters on the routine of the ward and operating room, on post-operative care, and on the disposal of paying patients. In addition, instructions are given on such procedures as pyelography, cholecystography, renal and other investigations, which if carried out in the manner prescribed would add considerably to efficiency, and often save the hospital staff a good deal of time.

The Library of the British Medical Association has lately received from Dr Frank A. Nyulasy a bound collection of some of the principal papers written at various times by his brother, the late Dr Arthur J. Nyulasy, gynaecologist and formerly surgeon to the Perth Hospital, Western Australia, and Vice president of the Section of Gynaecology and Obstetrics at the Australasian Medical Congress, 1920. In the obituary notice of Dr Arthur Nyulasy, which appeared in the *BRITISH MEDICAL JOURNAL* of May 24th, 1924, mention was made of his papers, some of which appeared in our own columns, some in the *Medical Journal of Australia*, and others in *Surgery, Gynecology and Obstetrics*, a few were published by himself in pamphlet form. Of his writings the most noteworthy perhaps were those on the supports of the uterus, and that in which he traced the cause of a typhoid epidemic at Perth to drinking water infected in the catchment area eighteen miles away.

The *Records of the Second Opium Conference*, which was held at Geneva from November 17th, 1924, to February 19th, 1925, have now been issued in two volumes. We published on August 22nd (p 356) a note about these two conferences based on Sir Malcolm Delevingne's report to Parliament. The first volume contains the text of the debates at the full meetings, and the second volume gives a record of the meetings of the committees and subcommittees. The large amount of valuable information contained in these two volumes will enable those who are interested in the difficult problems concerned to understand why no final conclusions have yet been possible. Attention is paid to the medical side of the question as well as to the social. A third publication, giving the list of seizures of opium reported to the League of Nations since 1921, has also been issued, and, in common with the two previous volumes, may be obtained from Messrs Constable and Co.

In *Some Maternity and Child Welfare Problems* a report is given of the lectures and round table talks at the summer school of maternity and child welfare during National Baby Week, 1925. The main subjects discussed were the formation of character and maternal mortality and morbidity. The speeches delivered are printed in full in some cases, and abstracts of others are supplied. Those who attended the school will doubtless be glad to have this account of the proceedings.

PREPARATIONS AND APPLIANCES

Cholecystography
 We have received from Mr W. Martindale samples of preparations of two drugs which can be used to render the gall bladder visible on x-ray examination. The substances are sodium tetraiodophthalate (Bromo-ray) and sodium tetraiodophthalate (Iodo-ray). This method of assisting the x-ray examination of the gall bladder was originally derived in America. It depends on the fact that phenolphthalein and its derivatives are excreted by the liver into the gall bladder, and that bromine and iodine compounds have appeared in these columns describing this method (for example, *BRITISH MEDICAL JOURNAL*, 1925, pp 54 and 1046). Mr Martindale has prepared solutions suitable for intravenous injection and also has a preparation on in capsule ('shilpale') form for administration by mouth. The dose is 25 grams of Sodium tetraiodophthalate in two injections at an interval of thirty minutes, one dose of 3 grams in 28 ccm of distilled water, dose by mouth up to a maximum of 66 grams.

British Medical Journal.

SATURDAY, DECEMBER 26TH, 1925

THE CLAIMS OF MEDICAL CHARITY

IN an issue of the BRITISH MEDICAL JOURNAL published on Christmas Eve we feel that little apology is needed for returning to the claims of medical benevolence. Last week we commended to our readers an appeal on behalf of the Epsom College Foundation and scarcely a month passes without some reference in these columns to the efforts of the Royal Medical Benevolent Fund to make a little money go as far as possible in the relief of distress. On the one hand there are elderly persons broken by fate and requiring help to mitigate their hardships, on the other there are boys and girls whose education and careers can be aided. The urgent need of greater support for efforts in these two directions is recognized by the British Medical Association, and the last three Annual Representative Meetings have been noteworthy for vigorous speeches on the subject. It was a matter seldom out of the mind of the late Dr Haslip during his trusteeship. In 1923 Dr Deuden, another keen critic of the existing state of affairs, gave a clear call for action by the Association. What he said then has we believe, never been disputed, because it is known to be true, he declared that the medical profession did not look after its own poor in the way it should and Dr Haslip went so far as to say that the position of the charitable funds was a disgrace to the profession.

Plain words at Portsmouth and in the following year at Bradford, had their effect. The Council of the Association was instructed to examine and report upon the situation, and a committee was set up. In approaching the problem two possible solutions were kept in mind. One was to try to get increased support for the existing organizations, the other was to start a new benevolent fund under the direction of the British Medical Association. The committee came to the conclusion and the Council agreed, that the wisest plan would be to endeavour to nouse by energetic action through the machinery of the Association a livelier interest in the funds already established. The Council accordingly recommended the setting up of a British Medical Association Charities Committee, charged with the duty of actively directing the attention of members to the misfortunes which befall necessitous colleagues and their families and of appealing for money to assist them, the sums so obtained being payable to a Charities Trust Fund and (unless earmarked for a particular purpose) distributed at the discretion of the Committee and the Trustees to the medical benevolent organizations. Dr Hawthorne, in putting this recommendation before the Representative Body at Bath explained how his committee after surveying the field had come to the conclusion that the value of existing charitable funds was limited solely by lack of money and that the best way in which the Association could participate in the work of benevolence would be by using its machinery to supply this defect. The chief duty of the proposed British Medical Association Charities Committee would he said, be the collection of funds for distribution to any professional benevolent organization in need of money and doing work which the Association approved. By this means it was felt that the Association as a body could most effectively shoulder its responsibilities.

The case for the setting up of a separate fund, unused and managed by the Association for the benefit of its members, was put by Dr J F Walker in a moving speech. When, however, Dr Deuden, who had set the ball rolling at Portsmouth, lent the weighty support of Manchester to the Council's scheme and Dr Bolam and others had testified to the quality of the work done by the existing benevolent funds, it became clear that the Representative Body would, by a large majority, accept the Council's advice. And so it comes about that the Association's Charities Committee is now in being and at work. A wise step has, we are sure, been taken, and it is to be hoped that every member will respond in the fullest measure to the Committee's appeals.

The hardship, and even actual want, of which many of the older applicants complain, is most distressing to recall, and the sums at the disposal of those who administer medical benevolence are altogether inadequate to meet the claims on their meagre resources. The annual subscription for membership of the British Medical Association falls due on January 1st. The moment is therefore at hand when we can give practical shape to the sympathy which must surely be felt by all, and particularly at this season for our colleagues who have fallen by the way and for the widows and children of doctors left in want. If every member of the Association would add to his next payment a sum for the credit of the British Medical Association Charities Fund, and would do this year by year a great reproach would be lifted from our profession.

EVOLUTION OF MORALS

THE hypothesis of mental continuity throughout organic evolution has been a great stimulus to the study of animal behaviour and investigations which have been made on animals under both natural and experimental conditions have been most fruitful for psychology. As a result of such studies it is now generally held that the powers of the human mind differ in degree rather than in kind from those of the lower animals and that rudiments for all mental functions may be discovered in animal behaviour. We may take the opportunity of the publication of two small books briefly to review the situation. The aim of both volumes is to examine the problem of good and evil from the standpoint of the biologist and philosopher respectively. The one is entitled *The Passing of the Phantom*,¹ by Dr C J Pitten, professor of anatomy in the University of Sheffield, who writes on definitely popular lines, the other is an historical introduction to ethics, by Mr Stephen Ward who endeavours to outline the development of abstract ethical speculations from the time of Societas to the present day.

The assumption is that the rudiments of what we describe as moral behaviour should be discoverable in animals and this is the subject considered by Professor Pitten who seeks to establish the thesis that moral functions like other mental functions are not exclusively human characteristics and that there is no breach of continuity in their evolution from lower animals to man. As evidences of a moral sense in the animal world he cites the behaviour of ants, the tenderness and anxious curiosity exhibited by gulls towards a wounded member of the flock, the mutual aid rendered by birds of different species against a

¹ *The Passing of the Phantom: A Study of Evolutionary Psychology and Moral* By C J Pitten, M.A., M.D., Sc.D. London, Keegan Paul, Trench, Trubner and Co., 2, 6d net.
Ethics: An Historical Introduction By Stephen Ward, London, H. Milford, Oxford University Press, 2, 6d net.

common enemy, the amiability of fierce predatory animals at certain times, and the harmony which often exists between domestic pets, such as the cat and dog—animals proverbially assumed to be hostile to one another. Perhaps the most striking instance of unconscious altruism in the animal world is the devotion unto death exhibited by many an animal mother when her young are threatened. It is curious that Dr. Patten should have omitted to mention this, because it is a fact of peculiar importance in any discussion on the evolution of ethics. Dr. McDougall has pointed out that the maternal attitude in such a case upsets the utilitarian theory of motives, for no nice calculation of the balance of pleasure over pain can be supposed to sustain her efforts, and she has certainly no unshakable belief in heavenly rewards or hellish punishments. She takes no thought for the morrow, anticipates neither good nor evil, neither pleasure nor pain, but, heedless of all consequences, makes one supreme self-sacrificing effort to fulfil the purpose of her being.

Though Mr. Ward makes a gallant effort to outline the trend of modern ethical thought, his treatment of the subject is not free from obscurity. If we understand his views rightly, he would maintain that the behaviour observed in the animal mother affords us an uncomplicated example of goodness and its manner of development. The animal which defends its young is not seeking to be good or self-denying, it is actuated by an inner impulsion to behave in a particular way, and in so doing quite unconsciously becomes a heroine. By aiming at something else, goodness, as it were, emerges. The fact that the goodness is unconscious makes it all the more good, for Mr. Ward holds that the essence of virtue consists in the fact that no man should know that he possesses it. Others can perceive it, but this, if he is to retain it, is just what he must not perceive. His defects he knows for himself, but he is good only for others. The artist can enjoy his work, the learned man his learning, but the enjoyment of our own goodness is denied us all. Goodness is like happiness, in so far as it is not best achieved by those who seek it directly, or, as Mr. Ward puts it, ideals are ethically more efficient the more their ethical aspect is ignored. Thus, morally the idea of self-realization is unsatisfactory, because it postulates an end and perfection in the self which it clearly does not possess. But if self-realization is urged for its own sake, as the sole condition upon which anything else can arise, the ethical difficulties disappear. So with the ideal of self-denial. If the self were moral, no one would wish to deny it, but in a non-moral setting self-denial is merely the other side of self-realization. Man denies himself, not because this is good in itself—which it is not—but because effort, endeavour, and work are the only conditions upon which he can be anything at all. If a man fulfils the condition of his being—namely, that he should be something—the rest follows. As he creates himself, so do truth and goodness supervene.

Mr. Ward contends that such considerations dispose of the theory that the moral and spiritual growth of man is in some sort an automatic process in which our sole concern is to see that the external conditions are favourable. Thus it has been argued that only good education is needed to make man wise, only a competence to make him virtuous, that by wealth and civilization life can be made easy. The difficulty of life is obviously a constant factor. New conditions create new difficulties, and though this is no reason for not removing such difficulties as we can, it should put a stop to vain hopes of an end to trouble.

Thus goodness, as Mr. Ward describes it, is not something imposed upon us from without, rather is it something which we unconsciously create ourselves in the process of self-realization. The more our potentialities are free to develop the better we shall be. The fact that activity is worth while for its own sake, apart from any material or moral consequences which may ensue, is exemplified in the life of all living creatures. Our civilization is not founded on any such principle, however, but on utilitarianism. It relies upon material rewards and punishments, upon praise and blame, and upon moral and religious sanctions, and it is generally considered that the disappearance of any of these three classes of incentives to good behaviour would wreck the whole of our existing social machinery. Many persons, indeed, view with much apprehension the decay of dogmatic religious beliefs, which is so marked a tendency of modern life. Dr. Patten does not hold this view, however, he considers that morality will develop as the revelational theory of ethics declines. In tracing the evolution of human morality he implies that superstitious fear, carrying with it notions of rewards and punishments, has been the dominant factor in the development of religious systems, together with the moral codes associated with them. Animal studies have led him to the view that the tendency to imagine spiritual essences in natural objects has had its origin in creatures below the human race, and he brings evidence to establish the proposition that the imaginative faculties which became so highly developed in humanity have been responsible for the evolution of superstition and conceptions of the supernatural. Most of us have observed the behaviour of a dog confronted with an unusual object which does not fit in with his experience of the nature of things. He barks and growls fearfully and angrily, and his hair becomes erect. But this is not all he betrays curiosity and feelings of attraction as well, exhibiting in his behaviour an exquisite example of conflicting impulses as he retreats and advances alternately. Curiosity generally wins, however, and he eventually makes friends with the unknown. Dr. Patten outlines the story of a similar conflict in mankind, we might, indeed, describe this simple episode taken from animal life as an abridged history of the moral and intellectual development of the human species. The fear of the supernatural or unknown has been the tap root of all the theologies which have evolved without breach of continuity from the time of primeval man until the present, and a form of "morality" must needs have accompanied these religious systems hand in hand, because they contained dictates regarding the meaning of right and wrong given forth through human instrumentality by supposed supernatural beings. As a biologist, however, Dr. Patten holds that the phantasies and speculations of human beings are themselves natural products and part of the scheme of evolution. Contained within and emerging from animistic conceptions of the universe are the germs of scientific thought and a moral outlook founded on the laws of nature. Like everything else in nature, human conceptions are subject to growth, change, and transformation, and there would appear to be no reason why the conflict between naturalism and supernaturalism should not eventually be resolved, and why philosophy, religion, and science should not ultimately fuse into a single body of wisdom. This is evidently Dr. Patten's hope, for he would seem to feel that by the patient study of nature we shall reach enlightenment and a moral outlook based, not upon fear and ignorance, but upon trust and knowledge.

THE STUDY OF HUMAN EMBRYOLOGY

It is a regrettable fact that our knowledge of human embryology is still very imperfect, and that the processes and conditions which result in abnormal development remain obscure. Although each year a very large number of specimens are obtained by medical practitioners, yet, owing to the absence of any central collecting station, the information obtainable from them is too often neglected. Professor J. P. Hill, F.R.S., head of the department of embryology at University College, London, has therefore issued an appeal to medical practitioners to preserve such specimens, and to send them to him together with clinical notes. The specimens particularly desired are embryos passed in abortion, with the membranes and decidua; tubal pregnancies, if possible unopened; uterine pregnancies, where the entire uterus has been removed for surgical reasons; necropsy specimens, if in reasonable preservation, emanating from cases where one or more periods have been missed and stillborn foetuses, particularly when abnormal. The specimens should be addressed to Professor J. P. Hill, or, if of large size, such as still-born infants, to Dr. H. A. Harris, Curator of the Museum, Department of Embryology, the Institute of Anatomy, University College, Gower Street, W.C.1. Collecting bottles filled with preserving fluid will be supplied if desired, and in the London area special arrangements could be made for the collection of large specimens. The fluid recommended is one part of ordinary formalin diluted with nine parts of normal saline solution. It is important that the specimen should be placed in a large amount of this solution as soon as possible after they have been obtained, and transferred to fresh solution twenty-four hours later. Professor Hill adds that the clinical data are of great value and should be sent with each specimen. A preliminary report will be sent to the medical practitioner immediately on receipt of the specimen, and later on, should it be required, more detailed reports will be forwarded concerning the estimated age and the pathological condition present. It is hoped in this way to form a collection of several sections of human embryos which will be valuable for study by competent investigators. Such a collection exists at present nowhere in England, and Professor Hill would, therefore, receive the active support of medical practitioners.

LONDON SCHOOL OF HYGIENE AND TROPICAL
MEDICINE

Work upon the foundations of the new London School of Hygiene and Tropical Medicine, which is to be erected in Bloomsbury to the design of Mr Morley Horder and Mr Vernon Rees, will shortly begin. While this is in progress the working drawings of the building will be completed and the scheme for the engineering services, which have been entrusted to Mr T J R Kienin, will be drawn up. Concurrently with these developments the board of management of the school is taking steps to supplement the facilities at present available for DPH students. A course in parasitology is already being given in the laboratories of the tropical division of the school, and arrangements have been made with Professor R J S McDowall to deliver there a course of lectures in physiology as applied to hygiene. In the tropical division some important changes are taking place. The school is shortly to lose the services of Colonel Alcock, director of the department of entomology, who is retiring under the age limit. He will be succeeded by Dr P A Buxton, who is now on his way home from Samor, where he has been engaged upon a research expedition sent out by the former managers of the School of Tropical Medicine. The post of assistant in the department of entomology has also fallen vacant through the retirement of Colonel Walton, but will not be

filled until Lt. Buxton has taken over his new duties. In the tropical division also the extended course which commenced in October has been strengthened. Wing Commander Whittingham will lecture on biochemistry, and a short course by Lieut. Colonel A. J. Craig on poisonous plants is being added to the curriculum and Colonel G. L. F. Strimmers has been appointed lecturer in tropical hygiene. The following subjects will be embraced by this course: tropical and subtropical climatology, personal hygiene, maternity and child welfare, housing in the tropics, food and dietetics, hygiene of food, water, exercise, and refuse, disinfection and disinfection, health measures. Hygiene of native labour in the tropics, disposal of the dead. Public health administration and organization in the tropics. Besides lectures on these subjects at Endsleigh Gardens, the students will be taken by Colonel Strimmers to see demonstrations, in and about London, in milk supply, water supply, sewage and refuse disposal, disinfection, and meat inspection, and a whole day will be given to a visit to the Army School of Hygiene at Aldershot. This extended programme in the study of tropical hygiene, although forming part of the general course of the tropical division, will be a self-contained course for which the school is prepared to accept a limited number of students at a fee of £6 6s. The lectures and demonstrations will extend over a period of about three weeks from January 13th to February 4th, 1926.

CLINICAL SIGNS OF DISORDERED CARBOHYDRATE METABOLISM

Dr MITLAND RAMSAY recently gave a lantern demonstration at the James Mackenzie Institute for Clinical Research, St Andrews, on the ocular manifestations of disordered carbohydrate metabolism. Excessive carbohydrate intake, continued over weeks or months, was, he said, responsible for the occurrence of phlyctenular conjunctivitis. The resulting disturbance of carbohydrate metabolism produced increased susceptibility to microbial infection, as evidenced by the ready occurrence of ulceration of the cornea, of eczematous eruptions, and of tuberculous disease of glands, joints, and bones. Pulmonary phthisis, however, did not occur, so far as he was aware. The children could tolerate carbohydrate if consumed at proper intervals with other food. But constant and irregular intake (these children are always eating) results in intolerance which must be regarded as a velocity rather than a weight. Abuse of tobacco by adults is in many respects analogous, but the metabolic disturbance in later life results from defective elimination rather than from excessive intake as in children. In many chronic glycosuric disturbance of sight is the first symptom to draw attention to the general condition. A number of the ocular lesions responsible for this were then described—for example, toxic amblyopia, sudden changes in refraction, retinobulbar neuritis, and hyperemia retinalis. In elderly glycosuric persons senile changes rather than the blood condition determine the occurrence of cataract, and Dr Ramsay argued that the term "diabetic cataract" should be reserved for cases in young diabetics. The etiology of cataract in the latter was discussed and the precautions preliminary to operation were described. The close resemblance of diabetic retinitis to the albuminuric form was illustrated and attention was drawn to the connection between protein and carbohydrate metabolism. In many cases both sugar and albumin were present in the urine, and the ophthalmoscopic picture was a combined one. Arterio sclerosis was a factor in both, but only affected the diabetic in later life while in the albuminuric arterial degeneration might be active at all ages. There must be a metabolic factor peculiar to each form of retinitis, but the evidence of this was only pronounced in the acute forms.

The outstanding feature in diabetic retinitis was the occurrence of hemorrhage, whereas oedema and the star-shaped arrangement of white spots in the macula was more characteristic of albuminuric retinitis. In forming a prognosis the outlook as regards life depended upon the state of the heart, blood vessels, and kidneys, and was better in diabetic than in albuminuric retinitis. The prognosis as regards sight was more serious in the diabetic form. The lecturer concluded with a plea for the routine use of the electric ophthalmoscope by the general practitioner, associated with the systematic analysis of the urine.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH

UNDER the Sanitary Officers Order of 1922, medical officers of health are required to prepare annual reports of their districts dealing with the general sanitary administration and vital statistics, but once in five years a fuller and more detailed report is required by the Minister of Health. As we announced at the beginning of the year, such a fuller report or "survey report" would be asked for in respect of 1925, a circular (648) has now been issued accordingly by the Ministry of Health giving detailed information about its preparation. Medical officers of health are required to describe comprehensively the progress effected in their areas during the preceding five years in the improvement of public health, the extent of changes made in the public health services, such as housing, maternity and child welfare schemes, and services directed to the prevention or cure of disease, and any special matter on which information is required by the local authority or considered desirable by the medical officer of health. It is hoped that the vital statistics issued annually by the Registrar General in respect of each urban and rural district will be received by the medical officers concerned at the beginning of February or the beginning of March, and that in consequence of this the survey reports may be completed not later than the middle of May. Medical officers of health are also required to report specifically on the administration of the Factory Acts in workshops, and a form (No 572) is provided for this purpose. Copies of this form when completed, are to be sent to the Home Secretary and the Minister of Health, as well as to the local authority and the county council.

VOLTAIRE AND MEDICINE

IN the second part of his paper on Voltaire and medicine read before the Section of the History of Medicine of the Royal Society of Medicine on December 16th, the President, Dr J. D. Rolleston, gave an account of Voltaire's illusions to anatomy and physiology, his advocacy of inoculation against small-pox, his interest in the history and ravages of syphilis, his attention to other matters connected with public health, his acquaintance with medical jurisprudence, and particularly his sceptical attitude towards historical cases of poisoning and his reference to various diseases of social importance, such as mental disorders, convulsive hysteria at the tombs of saints and ecclesiastics, alcoholism, and the king's evil. Voltaire's interest in public health was shown, not only by his desire to control certain contagious diseases, such as small-pox, by inoculation, and syphilis by the formation of a league of nations for combating the disease—a proposal not realized until 150 years later—but also by his allusions to other epidemic diseases, especially plague, typhus, and malaria, his condemnation of the insanitary condition of the Paris hospitals, the abuses connected with the administration of military hospitals, the crowded state of the Paris cemeteries, and the practice of burial in churches, as well as by his proposal

to found maternity hospitals for unmarried women. In concluding his paper, in which, as in a previous study of Lucian,² Voltaire's counterpart in classical antiquity, he had collected all the passages of medical interest, Dr Rolleston maintained that Voltaire, the founder of modern history and the most representative figure of the eighteenth century, deserved the attention of the medical reader, in that he was a powerful advocate of the profession, an uncompromising foe of quackery, and, by reason of his keen intellect and wide humanitarianism, was well in advance of his time in matters connected with public health, medical jurisprudence, and social medicine. The paper was followed by an epidiascope demonstration of portraits of Lady Mary Wortley Montagu, Trousseau, and Citheron the Great (who all figured in Voltaire's works and played an important part in the history of inoculation), of Astruc, from whose work on venereal disease Voltaire derived his knowledge of syphilis, and of Voltaire himself. Contemporary pictures were also shown of convulsive hysteria and touching for the king's evil, and a photograph of a wax figure of the dying Voltaire, which, according to Mr A. Forbes Stoddard, was probably the work of the Swiss artist Christopher Curtius, the uncle of the original Madame Tussaud.

CONTAMINATION OF APPLES BY ARSENIC

A few weeks ago we referred to the prosecution of a dealer for selling apples containing arsenic, and explained briefly how it is that arsenic is sometimes present on the peel of this fruit. A circular issued by the Ministry of Health on December 21st states that this matter has been brought to the notice of the Minister. Considerable quantities of arsenic have been found on the surface of certain imported apples, and two cases of arsenical poisoning have been traced to the consumption of imported Jonathan apples, samples of these apples which have been examined have shown various amounts of arsenic ranging up to 1/10 grain per pound. The contamination of apples by arsenic has been occasionally reported for a number of years, but the quantities of arsenic found by analysis on former occasions have generally been insignificant, and until recently no cases of illness have been traced to the consumption of such apples. As described in our note on December 5th (p. 1077), the amount of arsenic is liable to be especially large in apples grown in dry foreign climates where the fruit is reportedly sprayed during growth and the rainfall is not sufficient to wash away the deposit. The Minister understands that importers of apples from the regions concerned are taking such steps as are possible to secure the removal of the contamination from future consignments, but he desires to urge upon local authorities the necessity, especially during the next few weeks, of making full use of their powers under the Sale of Food and Drugs Acts, the Public Health Acts, and the Public Health (Imported Food) Regulations to protect the public by the examination of samples of apples likely to be affected, and by arranging for the withdrawal from sale of those found to be dangerously contaminated.

THE usual half-yearly indexes to the JOURNAL and to the SUPPLEMENT and LITERATURE have been prepared and will be published shortly, they will, however, not be issued with all copies of the JOURNAL, but only to those readers who ask for them. Any member or subscriber who desires to have one or all of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this desire.

¹ See BRITISH MEDICAL JOURNAL, October 31, p. 873.

Nova et Vetera.

THE AMPHIARON, OROPOS, ATTICA

A REFERENCE (October 31d, p. 624) to Amphiaron in Professor Gardner's address at the opening of the session of the Westminster Hospital has induced Surgeon Commander H. M. Brathwaite, R.N. (H.M.S. *Isalant*), to send as the following account of the Amphiaron, written from notes made during a recent visit to that shrine.

The Amphiaron is a temple-hospital situated about four miles south of Oropos Skali in Attica, Greece. As usual, a mythical and marvellous origin is ascribed to the institution. Amphiaron was a soldier-priest of Aigos, and fled from Thebes in Boeotia during the troublous times associated with Adrastus, leader of the expedition against Thebes in about 900 B.C. The story says that Amphiaron cut open the earth with his sword. Both he and his weapon were received and passed through the earth and came out at the site of the temple, where also a sacred spring gushed forth. Pausanias in his guide to Greece, volume 1, written about 160 A.D., says that Amphiaron fled to Chalcis and afterwards settled down and erected his hospital at this spring. The buildings are in a narrow valley, which runs roughly east and west, surrounded on three sides by well wooded heights, open to the sea, distant about half a mile, on the east. In the midst is a deep little gorge with ever-running water, formerly crossed by a wide bridge.

The rough track from Oropos Skali approaches the north-east end. The first buildings we meet are the ruins of the hot baths. Next is the Stoa, a colonnade about 100 yards long and 5 yards wide, closed on the north, open to the south. The roof was supported by numerous columns. The Stoa was provided with marble seats, so it is not difficult to visualize the patients walking or sitting talking here. Behind, that is north of the centre of the Stoa, is the theatre with seats of marble arranged in tiers round the semicircular cutting in the hillside. In front are five chairs with inscriptions dedicating them to ex-priests of the temple. At the western end of the Stoa is the temple. It contained a white marble statue of Amphiaron, now in the local museum and five altars, which still remain. The first altar is dedicated to Heracles, Zeus, and Apollo the Healer. The second to heroes and wives of heroes. The third to Hestia, Hermes, Amphiaron, and the sons of Amphiochus. The fourth to Aphrodite, Panacea, Iaso, Hygeia, and Athena the Healer. The fifth to nymphs, Pan, and the rivers Achelous and Kephalos.

The multiplicity of gods, goddesses, and demigods, and the accommodating way in which they shared the altars, is amusing. The absence of honours to Asclepius is noticeable. Before the temple is a big altar with a semicircle of seats in front. In addition there is a row of about twenty tomblike bases on which grateful and mighty patients placed statues of their noble selves. In Roman times the Greek statues were removed and replaced by statues of members of that conquering race.

These are all the buildings on the north side of the valley, and, considering their antiquity, they are in a fair state of preservation. On the south side is the sacred spring, approached by a flight of ten steps. It is dry now, the water comes out into the gorge. Behind the spring is the hospital. On the west is a row of twenty rooms for in-patients. Eastwards we come upon a hall, presumably for out-patients, a cookhouse, and numerous small rooms. These were probably for the attendants and visitors who came at festival times. These buildings were not so strongly built as those opposite and consequently are more ruinous.

Several tables of stone have been discovered inscribed with the rules and procedure of the hospital—as for example, "The Temple is in charge of the High Priest of Oropos."

He must visit it at least once every three days, and must stay at least ten days every month except at ploughing time [that is, from winter months]. He keeps the key of the money chest. The house governor lies in the hospital. He must issue a ticket to

every patient for admission, who must pay a fee of nine Obols and caution money five Drachmas. He must put the money in the Chest. He must keep good order, see that the treatment prescribed by the Priest is carried out, keep the men and the women separate. The left shoulder and the skin of Sacrificed Animals belong to the Priest," etc.

An interesting situation arose in Roman times. Some Romans refused to pay the fee to the god Amphiaron, arguing that a god had no need of fees. The priest of Oropos went to law about it, and eventually the case was taken to the Senate at Rome. The decision went against the priest and the god—a good example of Roman cupidity.

Very scanty records remain of the treatment patients received of the disorders from which they suffered, but the inscriptions and fragments of sculpture show that some surgery was done and that hydrotherapy and massage were employed. There is one specially interesting sculpture showing Amphiaron incising a patient's shoulder, the patient reclining on a couch, and the Sacred Serpent, emblem of medicine, sucking the poisonous matter out of the wound. The third figure shows the patient erect with outstretched arms, rendering thanks for his recovery.

This was the age of Hippocrates the Father of Medicine, so the art of healing had reached a high standard. But the mainstay of treatment was suggestion—the Oracle, as it was called. The patient was put to sleep and the priest, dressed as the deified Amphiaron, visited him and spoke, telling him what to do that he might be cured. He repeated his words many times so that when the patient awoke he believed that the god had come to him, and that if he carried out his orders he might recover. It was the custom for the patient on being cured to drop some silver or gold into the sacred spring.

This temple-hospital flourished for many centuries, as testified by the names, inscribed on the monuments of well known Greeks and Romans who came as patients. Notable among the latter is the name of Sulla.

My best thanks are due to Dr. Leonidas, who spent two hours on a hot Sunday afternoon (August 30th 1925) in showing me round and explaining everything, and who courteously received a party of twelve officers next day. The initial step was due to the kindness of Dr. Welter, whom I met at Aegina, where he is working for the German School of Archaeology.

THE HEALTH OF THE ROYAL AIR FORCE

IN 1921

THE report on the health of the Royal Air Force for the year 1921 has been published with commendable expedition, and is an admirably compiled document.

The average strength of the force for the year was 31,622, distributed among stations in the United Kingdom, Malta, Egypt and Palestine, Iraq and India. The admission rate for sickness and injuries was 463.6 per 1,000 of strength, excluding cases of forty-eight hours' duration or less, as compared with 473.8 in 1923. The invaliding rate was 9.5 per 1,000 as compared with an average of 12.3 for the previous three years, and the daily sick rate 22.4, as compared with 24.7. The death rate, however, shows an increase from 3.9 per 1,000 in 1923 to 4.5 in 1924. The average of the previous three years period was 4.3.

The chief cause of increase in deaths is a larger number of deaths from injuries. In classifying injuries a departure from the procedure adopted in previous years has been made. Injuries sustained during organized games are now classified as occurring on duty. The total number of injuries was 2,254 or 71.3 per 1,000 of strength, as compared with 60.3 per 1,000 in 1923. Nearly half the injuries of the lower limbs, and accidents during athletics, which were the chief cause of these, accounted for 36.4 per cent of the total number.

Injuries from flying accidents numbered 169 resulting in 69 deaths, or 7.5 per cent of the total number of injuries, as compared with 6.3 in 1923, 6.1 in 1922, and

6.4 in 1921. The increase is attributed to an increasing number of women pilots qualifying, and to an increasing number of women enlisted as passengers or undergoing instruction in aircraft. Aircraft is also increasing in size and carrying capacity, with consequent increase in the number exposed to risk of injury in the event of large craft being involved in an accident. Also the hours flown per fatal accident were higher in 1924 than in any previous year. A further factor was the fact that there were four collisions in 1924, with ten deaths. In 1923 no deaths were recorded from accidents of this kind. It would appear that the risk of collisions in the air is definitely on the increase. Several injuries due to miscrews and swinging the propellers are recorded, as in previous years. In 1924 there were two deaths from such accidents. Injuries are also recorded from starting motor engines, with no fatality, and a large number, 309 with 12 deaths, from motor cycle and motor car accidents. There were three wounds reported in action from Iraq, and two from Palestine. None were fatal. A table is given for the first time in these reports to show the age incidence of disease and injury. The age group under 18 years, a group serving only at home, shows by far the highest ratio per 1,000 of strength. In stations abroad the age group 24 to 25 suffered most. The lowest incidence was in the age group 30 to 34 years.

A section of the report contains tabular statements of disease and injury within the different trade groups enlisted in the Royal Air Force and among different types of units. The flying units, with by far the highest death rate, show the lowest ratio of incidence of disease. The highest disease ratio occurred in depots, ground schools, and armoured car companies. Among trade groups the disease ratio was highest in boys and lowest in aircraft hands. The high incidence among boys, nearly double that of other trade groups, was due to the number of admissions—205.0 per 1,000 of strength—for infections of the upper respiratory passages. In no other group did these infections cause a higher admission rate than 66.8 per 1,000.

Veneral diseases caused a remarkably low admission rate, only 16.3 per 1,000 of strength for primary admissions. This is the lowest on record. In 1923 it was 19.3 per 1,000. As in previous years, venereal disease was most frequent among drivers, the nature of whose work removes them to a certain extent from the discipline and supervision of their unit.

There was no outstanding prevalence of disease or epidemic either at home or abroad. The only station abroad with a high admission rate was Basia, where the ratio was 1081.2 per 1,000 of strength. This was mainly due, as in previous years, to malaria. Antimalarial measures were continued and amplified. Especially satisfactory was the success of the measures to prevent sandfly fever, a success due to the research work of previous years.

Among miscellaneous subjects dealt with are the work of the Central Medical Board, the medical officers' school of instruction and research laboratory, the physical efficiency of serving officers, the medical examination of recruits, laboratory work at Air Force hospitals, the transfer of casualties by air, and dental treatment. The physical assessment of 2,284 officers in respect of vital duties shows a higher percentage than previously (89 per cent at home and 92 per cent abroad) of officers fit for full flying duties. A new apparatus was devised for research work on psychomotor responses in relation to flying. The causes of rejection of recruits were similar to those of previous years, dental defects, diseases of the heart, and deformities of the feet leading the list.

A feature of the report that is of general interest to the medical profession, and especially to hospital staffs, is the description of the special method employed in the Central Laboratory for the routine pathological examination of all officers involved from abroad. A point is made of the advantage of carrying out the tests at a definite hour of the day, 10 a.m., in order to render the results of all examinations comparable and void the variations that occur with the time of the day in certain physiological processes. All material is collected within two hours and the tests completed in twenty-four hours. The tests are excep-

tionally thorough and comprehensive. The transfer of casualties by air is now the recognized method in Iraq. The total number carried in 1924 was 81, a small number compared with the numbers carried by French aircraft in Syria and Palestine. A short description is given of three types of aircraft used for transfer of casualties. Only one of these is a specially designed aerial ambulance.

England and Wales.

AN OUTBREAK OF MILD SMALL-POX

THE county medical officer of Lancashire has issued a report of a small-pox outbreak in the borough of Ashton under Lyne and adjoining districts. Though the cases numbered only 116, the report extends to twenty-eight foolscap pages, but it is not a line too long, indeed, it shows how a limited outbreak can be the subject of a detailed and intensive study which would be almost impossible for an extensive epidemic. The report ends with a series of observations and conclusions, but the particulars of the cases are set forth with so much detail that anyone who chooses has abundant material on which to base a judgement of his own on every point. Dr. Butterworth explains that for a large part of the information used in the preparation of the report he is indebted to Dr. Cronk, assistant county medical officer. Careful clerical work in the recording of day-to-day occurrences has been a noteworthy feature of the administrative measures. Another feature was the co-operation between the local sanitary authority and the county staff, the personnel of the latter having been made available to supplement that of the former.

The outbreak began in June, 1924, owing to missed cases and the prevalence of chicken-pox. The spread was favoured by crowded attendances at theatres, by employment exchanges and billiard halls, and by deliberate concealment of cases. From mid-July to mid-September was a period of increasing activity, from mid-September to the beginning of December of maximum intensity, and to the end of January, 1925, of diminishing virulence. The outbreak was of the mild type common in this country at the present day, and no deaths occurred. Infectivity was of no great intensity.

The efficiency of vaccination performed before infection was shown by the hospital statistics. The age of the youngest case of small-pox after vaccination in infancy was 22 years. While it is pointed out that vaccination after infection must have prevented the development of many cases, yet in 19 the disease did develop, the interval between infection and vaccination being from two to seven days in 12 cases for which the facts were ascertainable.

It was found possible to persue very nearly all the contacts to accept vaccination. Among 249 contacts in houses investigated, 22 developed small-pox, 17 being secondary cases, 4 from the same source as the primary case, and 1 from a totally different source. Among 19 contacts primarily vaccinated within twenty-four hours of infection no case of small-pox occurred, among 24 vaccinated within two days of infection one case developed small-pox, and among 55 contacts vaccinated more than two days after infection there were 13 cases of small-pox. These figures relate to primary vaccination of contacts. There were also 86 contacts who, having been vaccinated in infancy, underwent revaccination after exposure to infection, and none of these developed small-pox, though in 10 the revaccination was more than five days after infection, and in 31 it was done on the fourth or fifth day. The intervals between infection, onset, and rash are of epidemiological and administrative interest, and are especially worth study in the mild type of small-pox. They were carefully noted, and in 37 cases the information can be regarded as being accurate from repeated questioning and daily observation. The interval between infection and onset varied between eight and nineteen days, the mean being thirteen days. Two thirds of the cases occurred after eleven, twelve, or thirteen days (inclusive). Observation of contacts was maintained for eighteen days. The time elapsing between onset and development of the rash was two days in 6 cases, three days in 9, four days in 11, and

five days in 5. The mean was three days, and two thirds of the cases conformed to the mean. Hospital isolation was regarded as of only secondary importance to vaccination, but of 114 cases 55 were not notified or removed within less than forty-eight hours after appearance of the rash, in 3 cases the interval being more than seven days.

As regards the question whether classical and mild small-pox can be looked on as different diseases, Dr. Butterworth is not a dualist. After discussion of various points his views are summed up as follows: (1) The type of small-pox met with in an epidemic remains constant throughout that epidemic, (2) on seeing an individual case of small-pox, no conclusion can be formed as to the outcome of cases infected thereby, it follows that an isolated case of small-pox may be the start of an outbreak of the mild or classical variety, and also that in the course of an epidemic, unless each case is traced to its origin, a case of classical small-pox may creep in under the guise of mild small-pox. With the type of disease now present isolation of cases and vaccination of contacts are insufficient, even with constant vigilance, to bring an epidemic once fairly started to a rapid conclusion.

Conclusions

The conclusions drawn are as follows:

- 1 The epidemic at Ashton under Lyne was one of small-pox of the mild type.
- 2 No clinical feature of the disease could it be distinguished from classical small-pox or in its relation to vaccination.
- 3 The infectivity of the disease was not great on the whole but varied with different cases and at different periods of the epidemic.
- 4 The ascertainment and vaccination of contacts with immediate isolation of cases must be instituted immediately and energetically for rapid control.
- 5 The infection is kept going chiefly by "missed" cases there is no evidence in favour of "carriers" playing an important part in the spread of small-pox during an epidemic, whatever may occur in interepidemic intervals.
- 6 Schools should be kept open.
- 7 All public meetings should be discouraged as much as possible, they are a potent source of missed cases.

KING EDWARD'S HOSPITAL FUND

The Prince of Wales, on December 15th, presided over the distribution meeting of the King Edward's Hospital Fund for London, and read a letter from the King expressing satisfaction that the fund had been able to increase its distribution by £10,000, and that with the extended area of its operations it had now made grants to a larger number of hospitals. Lord Sturrit of Wortley, who moved a resolution recording the general council's deep sorrow at the death of Queen Alexandra, and its sympathy with His Majesty and the Royal Family, referred to the great assistance that Queen Alexandra had given to the hospitals of London. It was her special delight to be ever giving to the needy or visiting the sick.

Lord Revelstoke, honorary treasurer, reported an increased distribution of £245,000 out of the income for the current year, as compared with £235,000 in the previous year. Although receipts from legacies were below the average, some timely donations had been received. The British Charities Association had increased its contribution from £15,000 last year to £20,000, and a further amount of £85,485 had been received from the estate of Lord Mount Stephen. From the Wells legacies, which were estimated at £200,000, the amount received to date was £162,240, out of which £138,000 had been allocated so far. Sir William Collins, making the annual statements on behalf of the League of Mercy, said that the league associated itself with Lord Cave's Committee in the hope that the policy of obtaining contributions from patients would not prove detrimental to the indigent sick or prevent the admission of the very poor, for whom the hospitals were primarily intended. The league would be in a position to hand over £15,000 this year, which would make its total contributed to the King's Fund £383,034. Beyond this the league was making grants of £9,845 to extrametropolitan hospitals with the assistance of the British Charities Association, which had contributed £5,000 towards that distribution.

Sir Cooper Peeny, presenting the report of the Distribution Committee, said that the amount to be allocated this year was, apart from the sum provided by the British Charities Association, £243,000, as against £233,000 in each

of the two previous years. The number of hospitals applying for grants had increased from 118 to 133. Taken as a whole, the hospitals continued to maintain in 1924 the improved financial position which had been gradually reached since the crisis in 1920, and for the second year in succession there was an excess of income over expenditure, though less than in 1923. The proportion of hospitals with deficits had fallen from 48 to 46 per cent. Additions were continually being made to the number of beds available, so that a larger income was still required to meet the remaining deficits and to cover the growing work. The maintenance grants had, therefore, been increased this year to £214,075, as compared with £197,275 in 1924. This had involved a decrease in the grants in aid of schemes of capital expenditure, which amounted to £28,925, as against £35,725 in the previous year.

Maj. Harold Wenner, honorary secretary, presented a schedule containing a list of awards to hospitals, including recovery and convalescent branches. Among the larger grants were:

London Hospital £14,625 Guy's Hospital £12,500 St. Thomas's Hospital £11,000 Royal Northern Hospital, £8,700 University College Hospital £8,500 King's College Hospital £7,500 Middlesex Hospital £7,400 St. Bartholomew's Hospital £7,000 St. George's Hospital £7,000 Westminster Hospital £6,150 St. Mary's Hospital £6,000 Metropolitan Hospital £6,000 Royal Free Hospital £6,000 Royal National Orthopaedic Hospital £5,500 West London Hospital, £5,500 Miller General Hospital £5,225 Prince of Wales's General Hospital £5,200 Queen's Hospital for Children £4,250 Queen Mary's Hospital for the Pauper £4,150, National Hospital for the Paralysed and Epileptic £4,000 Charing Cross Hospital £4,000 Hospital for Sick Children £4,000

After Sir Cooper Peeny had presented the report of the Distribution Committee with reference to convalescent homes not attached to particular hospitals, and the report of a committee on the special distribution to hospitals out of the Wells legacies, the Prince of Wales pointed out that the area of the King's Fund had now increased from 255 square miles to 380, while the number of hospitals helped had risen from 118 to 133. The amount of the ordinary distribution during the year was £245,000, the Wells legacies produced £57,000, so that the combined total was £302,000. About two-thirds of the ordinary distribution of £245,000 came as income from investments, and about £82,000 had to be raised in the year. But although annual subscriptions had always been smaller than was desirable, yet this year they had shown a welcome increase—largely in the form of seven-year agreements, many of them so worded that the subscribers gave the King's Fund the benefit of any income tax saved by the agreement. Though the income of the fund had been increased, the demands were also growing. Fifteen new hospitals had been added to the list, and the general hospital expenditure was being continually increased by the discoveries of medical science and by the provision of additional beds. There was, therefore, continued need for generous subscriptions. In the matter of extensions along the King's Fund, by devoting the Wells legacies largely for the purpose, had been helping to provide 697 additional beds, which would all have to be maintained. The Management Committee had also concluded that there was an immediate need to expedite schemes for the provision of another 2,000 beds, the Voluntary Hospitals Commission had accepted this estimate for London, and had added another 8,000 beds for the rest of England and Wales. The Wells legacies acted as a stimulus to enable hospitals to raise the money for extensions more rapidly than would otherwise have been possible. An important piece of work this year had been the further revision of the revised uniform system of hospital accounts, which had been occupying the Hospital Economy Committee for many months, and was now nearly finished. The propaganda committee was arranging a programme of lectures in the schools on the work of the voluntary hospitals, many hospital experts were taking part, and the lectures were arousing much interest. Captain O. E. Warburg, moving a hearty vote of thanks to His Royal Highness for presiding, said that the London County Council viewed with the greatest gratitude the wonderful work that had been done by King Edward's Hospital Fund under his presidency. The Council appreciated the Prince's energy and public spirit in forwarding the great work.

Ireland.

ROYAL MEDICAL BENEVOLENT FUND SOCIETY

IN its eighty-third annual report the Central Committee of the Royal Medical Benevolent Fund Society of Ireland states that the number of grants awarded in the year was 86, an increase of 3 as compared with the preceding year. Of these, 5 were made to medical men, 8 to orphans, and 73 to widows. The amount disbursed in grants was £1,755, as compared with £1,540 in 1923-24, and the average amount of each grant has increased from £18 10s 7d to £20 8s. In presenting the audited balance sheets of the General Fund and of the Osborne Fund, the committee once again expresses thanks to the honorary secretaries of the branches for their work, and to the individual subscribers for their support. The income of the General Fund from all sources amounted to £2,097. In this is included £422, the amount of income tax refunded for two years. Dividends and interest yielded an increased income of £48 19s 2d. Subscriptions paid through branches, including those of the Dublin area, increased by £21 9s 6d, while those paid through the central treasurer increased by £20 5s. The British Medical Association is thanked for collecting £26 13s. Donations amounted to £21 10s, being a life membership payment of £10 10s by the President of the Royal College of Surgeons in Ireland, Mr R. B. Mansell, and £11, the "thankoffering of a widow" who at a time of due need received a special grant from the Fund. The Irish Medical Association sent £20, and the Dublin Clinical Club £5 5s. No legacies were received during the year, nor was any addition made to the invested capital of the Fund. At the beginning of the year the Osborne Fund stood indebted to the General Fund to the amount of £220 18s 5d. On June 18th, 1924, the Central Committee, having reviewed the position of the Fund, decided that charges on the Osborne Fund should be suspended until it showed a credit balance. Accordingly all grants have been charged to the General Fund, and at April 30th, 1925, the indebtedness of the Osborne Fund had been reduced to £109 12s 8d. Looking to the future, the Central Committee found some factors which caused it anxiety. The fall in the capital value of railway stocks had been referred to the trustees for consideration and action. The country was, the committee noted, passing through a period of financial stress, and medical men had suffered in common with all classes of the community. That the subscription list had shown some increase was a matter for congratulation, those who subscribed did so generously and merited thanks, the many who had not hitherto helped the Fund were asked to give their support so that the society might be able to grant relief to those who went to it in their time of need. Only by widening the field of support could the Fund be maintained on a sound financial basis. At the annual meeting the following resolution was passed:

That this meeting desires to convey its thanks to the officers of the branches for their valued aid in the society's work, and also to all those who have subscribed to its funds. It urges the claims of the society on the many members of the profession who have not hitherto contributed as it is only by increased support that it can be maintained on a sound financial basis.

Scotland.

EDINBURGH CHAIR OF PUBLIC HEALTH

THE Edinburgh University Court has appointed Colonel P. S. Lelan, C.B., C.M.G., F.R.C.S., to be Professor of Public Health in the University in succession to Professor Hunter Stewart. Professor Lelan was born in Canada in July, 1871, and received his medical education at St. Mary's Hospital, London, and having entered the Royal Army Medical Corps, had a wide experience of army organization and hygiene. Until recently, when he was appointed inspector under the Home Office in succession to Sir James Russell, he had been Professor of Hygiene at the Royal Army Medical College. During the South African war he served as a civil surgeon, and from 1906 to 1912 was with the

R.A.M.C. in India, where he was concerned particularly with sanitary work. In the Egyptian Expeditionary Force he acted as Assistant Director of Medical Services at General Headquarters. Professor Lelan is the author of a number of scientific publications, including a textbook on *Sanitation in War*, which enjoyed great popularity upon its appearance in the early months of the great war. His capacity as a teacher, writer, and organizer was widely recognized in the posts which he has held in connexion with the army. During the war he rendered important services in experimenting upon the action of poison gas, and in devising methods of protection. At the same meeting of the Edinburgh University Court, Dr. William Robertson, F.R.C.P., medical officer of health for the city of Edinburgh, was appointed to be director of instruction in sanitary administration in connexion with the University.

INSPECTOR UNDER CRUELTY TO ANIMALS ACT

The Home Secretary announces that he is about to appoint an inspector under the Cruelty to Animals Act 1876. The post is permanent, and is pensionable in accordance with the general rules governing pensions in the Civil Service, and the appointment will be subject to a period of probation. The salary will be £800 a year, with Civil Service bonus and the usual travelling allowance. The inspector will be required to give his whole time to his duties, and to reside in Edinburgh for the time being. Candidates for the post who possess the scientific qualifications required for the work and are not over 50 years of age, should apply to the Private Secretary, Home Office, Whitehall, London, S.W.1, from whom further information may be obtained. Applications should be accompanied by one or two testimonials and particulars of the candidate's qualifications, and should reach the Home Office not later than January 15th, 1926.

PREVENTION OF DIPHTHERIA AND SCARLET FEVER IN ABERDEEN

A memorandum has been issued by Dr. J. Purvis Kinloch, M.O.H. Aberdeen, on the methods now available in that city for the prevention of diphtheria and scarlet fever. During the past ten years there have been in the city of Aberdeen 4,563 cases of diphtheria, with 254 deaths, and 5,526 cases of scarlet fever, with 215 deaths. For the treatment of these two diseases during the ten years in the City Hospital alone an expenditure of £150,000 has been incurred. It is obvious, therefore, that any method which lessens the incidence of these diseases will bring about not only a saving of human life, but a considerable decrease of municipal expenditure. Of the cases of diphtheria 73 per cent. and of the deaths 95 per cent., and of the cases of scarlet fever 82 per cent., and of the deaths 95 per cent., occurred in children under 15 years of age. Children, during the first six months of life, have a passive immunity to these diseases derived from the mother, but this rapidly falls off, and from the age of 6 months they become very susceptible to both diseases, remaining so for some years, until they slowly develop a natural immunity. After giving accounts of the Schick test for susceptibility to diphtheria and of the Dick test for susceptibility to scarlet fever and of the methods devised for producing active immunity against the diseases in children found to be susceptible, Dr. Kinloch states that research work at Aberdeen City Hospital has proved that toxoid-antitoxin used for protection against diphtheria can be used in admixture with scarlatinal streptococcus toxin for protection against scarlet fever, and thus one series of injections can be given to produce immunity from both diseases. The memorandum recommends that this plan should be carried out as soon as possible after children are 6 months of age. The Aberdeen Town Council in October, 1925, resolved that material should be made available with the object of having active immunization against the two diseases as widely as possible adopted in the city. The method recommended to be followed is as follows:

Susceptibility Tests.—In the Schick test for susceptibility to diphtheria 0.2 c.c. of a diluted diphtheria toxin is injected intracutaneously into the front of the left forearm while

is a control, the same amount of diluted toxin, inactivated by heat, is injected into the skin of the right forearm. The reaction is read after forty-eight hours, and if a circumscribed area of redness measuring from 15 to 30 mm has appeared round the point of injection the reaction is considered positive. The reaction reaches its maximum intensity about the fourth day and may persist for about a week, but is not painful and does not cause any harmful effect. The Dick test for scarlet fever closely resembles the Schick test, and consists in the intracutaneous injection of 0.2 ccm of a diluted toxic filtrate obtained from a broth culture of scarlatinal streptococcus. The toxin is standardized by finding a dilution (known as 1 skin dose) which gives a negative reaction in convalescent cases of scarlet fever but gives a positive reaction in young susceptible children. A similar dose of inactivated control filtrate is injected into the skin of the right forearm. A positive Dick reaction is said to be present when a light red flush of 15 to 30 mm diameter appears round the point of inoculation in a few hours, reaching its maximum in twenty-four hours. This dose is also quite painless and harmless.

Method of Immunization.—When children, by the above method, are found to be susceptible, a suitably prepared injection of toxin is given to produce active immunity. In diphtheria toxin is prepared by exposing diphtheria toxin to the action of 0.1 per cent formalin at 37°C for about four weeks. This is mixed with a small amount of antitoxin (27 units in 20 ccm of toxin). This mixture is diluted 10 times and 1 ccm is used as the dose for producing immunity. Three injections of 1 ccm of the toxoid-antitoxin mixture are given at weekly intervals subcutaneously into the upper arm near the insertion of the deltoid muscle. Active immunity gradually develops in one to six months and tides the children over the susceptible years until natural immunity manifests itself. In the case of scarlet fever active immunity is obtained by the administration subcutaneously of three graded doses of the toxin injected at weekly intervals. The first injection consists of 500 skin doses, the second of 1,500 and the third of 3,000 or more skin doses. The active immunity from scarlet fever takes about two weeks to develop and thus the method is useful in stopping outbreaks of scarlet fever as contrasted with the inability of immunization against diphtheria to control outbreaks of the latter disease, owing to the long time required for active immunity against diphtheria to develop.

The memorandum suggests that medical practitioners should direct their main activities in this matter to securing the protection of children in the period from 6 months to 6 years of age, and it is proposed to extend the campaign for immunizing children by making the susceptibility tests (Schick's test and Dick's test) widely applicable to the child population at child welfare centres and at school clinics. The materials necessary for immunization will be obtainable from the City Hospital laboratory or from the chief resident medical officer, and among these are combined diphtheria and scarlatina prophylactic (toxoid antitoxin and streptococcus toxin mixture) for producing active immunity to diphtheria and scarlet fever concurrently.

Correspondence.

THE TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

SIR,—In the discussion on the treatment of acute intestinal obstruction (JOURNAL, November 28th, p. 993), the question as to how drainage of the upper end of the jejunum can relieve obstruction low down in the small intestine—that is, how opening the bowel at its highest level above the obstruction is going to relieve the distension of the coils lying below it—does not seem to have been considered.

The explanation given by Mr Victor Bonney (JOURNAL, 1916, i, p. 583)—the view on which his advocacy of this operation of high jejunostomy is based—is that in obstruction of the small intestine the coils for some distance above the obstruction contain no fluid, but are only distended with gas, whereas the upper coils are distended with fluid, and that therefore these must be drained by a high opening of the jejunum, and that it is useless to open a coil just above the obstruction, as here the bowel is only distended with gas. Mr Sampson Handley (JOURNAL, 1916, i, p. 632) pointed out that he had not been able to verify Mr Bonney's description of a separate gas-containing and fluid-containing portion of the obstructed and distended small intestine, nor have I ever found evidence of it on the operating table, or in the post-mortem room, and it would be interesting to know the experience of other surgeons. Mr Bonney says he has obtained evidence in favour of his view in cases in which, on making an opening into the obstructed bowel low down, nothing has come away, and the patient has died

with unrelieved obstruction accompanied by facial vomiting. But this is no proof of his view as to the presence of separate air- and fluid-containing segments of intestine. It is notorious how greatly distended small intestine above a mechanical obstruction is often not relieved by opening the bowel at the lowest level, any more than it may be by removal of a mechanical obstruction such as the division of a constricting band, and surgeons have always believed that this was so because the greatly distended bowel was paralysed and knicked. In such cases nothing short of mechanically emptying the distended coils, by passing them through the fingers—"milking" them, as it is sometimes called, or the adoption of the device advocated by Sir Berkeley Moynihan—will suffice. But this is a very shock-producing procedure in these very bad cases of life obstruction. If, when operating for obstruction of small intestine, we puncture one of the greatly distended coils, we shall evacuate some gas and fluid but only from that one coil; no more comes from the equally distended coils above it because they are too paralysed and knicked.

We may be sometimes tempted to think of distended small intestine as if it were one freely communicating tube. It is not. Every time, when it is greatly distended, becomes a most definite kink the walls of which are tightly pressed together by the distension of surrounding coils, and only vigorous peristalsis above can force fluid and gas through it. This is why, if we make an opening in the distended coils low down, expecting thus to drain them, nothing may come away.

Mr Victor Bonney's view as to why only the upper coils above the obstruction are distended with fluid, and not the lower ones, seems to me hardly justified by the facts. He says the reason is that these upper coils have become infected by the *Bacillus coli*, and he relates a case (loc. cit.) in which, for some feet above a septic focus in the small intestine, the contents of the coils resembled stereococcus vomit, because these coils had become infected from the suppurating focus. But in a case of intestinal obstruction there is not necessarily, or even usually, a septic focus in the bowel, and it is only from putrefactive changes due to the obstructed contents of the small intestine that they come to resemble faeces. Why, then, should this change take place only in the upper end of the obstructed intestine? One would expect it first, and most marked, close above the obstruction, for there the fluid would have been longest retained. Why, then, should the coils of intestine nearest the point of obstruction only contain gas, as Mr Bonney believes?

Of course, it is obvious that the cessation of faecal vomiting, or indeed of vomiting of any nature, from the performance of a high jejunostomy must be a great asset to the patient, but what we want to know is how all the distended coils below the level of the jejunostomy are emptied by it. The surgeon who opened the discussion spoke of a siphoning out these distended coils, but we cannot siphon and siphon out distended and knicked coils of small intestine as we can the bladder, because when the coils are folded on themselves and knicked, as I have just pointed out, each coil is separated off into a different compartment.

If a reversal of normal peristalsis all along the distended coils (which may be the greater part of the small intestine) takes place so that they empty themselves upwards, then our view that paralysis and kinking is the cause of the persistent obstruction, after the relief of a mechanical one, must be wrong. Yet if these coils are really active, how is it that they empty themselves upwards, and not in the normal direction? If as Mr Bonney believes the upper coils are distended with fluid, and the lower with gas, as soon as it was possible for one coil to empty itself into another what is to prevent (what we should expect would happen) the fluid in the upper coils passing down the intestine and displacing the gas upwards? But it may be that the high jejunostomy just tides the patient over a very critical period, in which, without it, death would have occurred from incessant faecal vomiting, and that then (perhaps in twenty-four hours after the jejunostomy) the paralysed bowel begins to pass on its contents in the normal direction and the obstruction is removed. Whatever the explanation of its action may be, undoubtedly this high jejunostomy seems to have been a life-saving operation in many cases.

It is very instructive to note the nature of the six cases first reported by Mr. Bonney (loc. cit.) in which he performed this high jejunostomy for intestinal obstruction. One of them was a 'general' septic peritonitis, one a paralytic condition of the lower ileum and colon following hysterectomy, one appears to have been a paralytic condition of the bowel following operation for ectopic gestation without peritonitis, one obstruction from adhesions which could not be removed, and one paralysed bowel associated with pelvic suppuration. Thus the operation was originally performed not for persistent obstruction, in distended coils of small intestine, after a mechanical obstruction had been removed, but for some form of paralytic obstruction either not primarily due to a mechanical block or strangulation, or in which such block could not be dealt with. The operation was very successful in these cases—indeed, it proved a life-saving operation in desperate conditions, but Sir William Taylor has not apparently had such success with it, for he deplores the very high mortality he still has in operation in late cases of acute intestinal obstruction.

Mr. Rowlands, when, in 1916, discussing the advisability of Mr. Bonney's suggested high jejunostomy (*JOURNAL*, 1916, 1, p. 739), said he considered the right level to drain the intestine was 12 inches above the obstruction. Speaking of Mr. Bonney's high jejunostomy he says: "My experience is that it is neither necessary nor wise to drain the intestine so high up. It is not necessary for drainage at least 12 inches above the obstruction usually proves successful. It is not wise because every inch of small intestine is valuable for digestion and absorption." In the discussion Mr. Rowlands does not refer to the level at which he now drains. It is surprising to me that Mr. Rowlands is able to say that drainage just above the level of the mechanical obstruction in his practice has been "usually successful," for it is in these desperate cases of great distension and kinking of coils of small intestine that such an opening is often attended with failure.

Mr. Sampson Handley (p. 995) thinks that persistent obstruction after the removal of a mechanical obstruction, such as the division of a band, may be produced by the loss of power in a loop which has been very tightly strangulated, so that it does not pass on its contents. A strangulated loop of small intestine, whether strangulated within the abdomen or in a hernial sac, is not usually of any great length, and if the intestine above it is still active, and itself not obstructed by kinking, it seems to me very difficult to conceive that it cannot force on the intestinal contents through a short length of strangulated bowel even though it is paralysed. If the strangulation of the small intestine to a marked degree, but only involving a small length of the gut, were really a cause of persistent obstruction, surely such obstruction would be much more frequent than it is after herniotomy.

Last there should be any misunderstanding may I say that in this letter I, of course, only refer to the operative treatment of the late stage of obstruction—cases in which time has elapsed for this very serious great distension of coils above the level of the mechanical obstruction—I am, etc.,

CHARLES A. MORTON

INTESTINAL OBSTRUCTION

WHAT THE GENERAL PRACTITIONER THINKS

SIR—So the poor general practitioner has been found guilty—by Sir William Taylor this time—of one more heinous offence. Not sufficient that he should be responsible for all maternal morbidity and maternal deaths in childbirth he is now branded as a criminal because the death rate of intestinal obstructions is so high. At the present rate it would appear that all virtue has departed from the unhappy practitioner, and the sooner he gets out of business the better for everyone. Perhaps polishing the brass plates and acting as "receptionist" for those millionaire ones, the real embodiments of light and learning would be a fitter occupation, and keep him more in the place where he obviously ought to be. For one with such criminal propensities the post of secretary would obviously offer far too great temptations to retain for himself a small share of the fees which a Divine Providence and a discerning public should run without stint upon those

fortunate ones who never could make a mistake in diagnosis or technical judgment but they tried ever so sorely.

But, seriously, is it not time that more restrained language was used by some of the leaders of the profession in calling attention to the alleged shortcomings of the many of their professional brethren? Over-emphasis in the layman only recoils upon the head of the author, and I venture to suggest that remarks like those made by Sir William Taylor in the Section of Surgery at the Annual Meeting at Bath (*BRITISH MEDICAL JOURNAL*, November 28th, p. 995) only serve to make him ridiculous. It is admitted that early diagnosis in the majority of cases of obstruction is a very difficult matter, and may call for the very finest judgement and clinical instinct. We could all of us, no doubt, cite instances within our own experience where clinicians of deservedly high repute have been caught out in cases of this kind. An early diagnosis may be best with pitfalls not alone for the ignorant and unwary. On such occasions to my mind which I encountered when a resident in a large London hospital.

One night in ancient Jew, grave of men and pitiable of aspect presented himself before me with the statement that his bowels had not acted—a not very unusual complaint amongst his race and in that neighbourhood. A few tactful questions elicited the information that it was his custom and had been for a very long term of years previously, to defecate once a week, and that on Tuesday evening. The reason for his visit to the hospital was that on this particular Tuesday evening, in spite of a strict observance of the proper ceremonial, he had tried and failed. An examination did not reveal any suspicious signs either in the abdomen or in the patient's general condition. Accordingly a select assortment of the finest aperients available—and in spite of the need for economy the hospital was very generous in this respect—was administered on the spot, and the patient, fortified with these and much sound advice was sent home. Some hours later he returned, this time on a stretcher, and with a belly blown up like a balloon. He was operated upon forthwith, a volvulus of the sigmoid colon was found, and in due course he was gathered to his fathers.

There is a moral to this story. What the practitioner requires and eagerly looks for is sound guidance and instruction, not vituperation—I am, etc.,

C. J. CORDON TAYLOR, M.D. Oxon

Brighton, Dec. 11th

BLOOD PRESSURE IN THE SCHOOL CHILD

SIR—In his most interesting address to the Section of Medicine at the Bath meeting of the British Medical Association Lord Dawson gave his support to the view that the beginnings of hypertension were often to be found in youth, and incidentally suggested that school medical officers might do useful work in directing their attention to blood pressure in the school child. In 1922-23 I had occasion to measure the pressures of over 1,000 boys in London schools, the results of which research have been published,¹ and those boys who then presented suspiciously high systolic pressures without any obvious heart lesion have recently been followed up. Of the boys in the category who have now left school Lord Dawson referred to 3 whom he has had carefully re-examined, of whom 2 have now developed a definite cardiac enlargement. Some 550 of the total boys are still at school of the age 11, or about 2 per cent. give readings in excess of what I have tabulated as the 'suspicious' limit for their age, and having recently followed up these cases also I think it may be of value to give briefly the results of this inquiry. Apart from their unduly high blood pressures these 11 boys were apparently in normal health when I saw them two to three years ago, and no intimation was given either to the headmaster or the school medical officer with regard to the pressure readings obtained, so that their subsequent dealings with the boys were not biased in any way. I find that their recent progress and present condition are briefly as follows.

No. 1 now aged 13 has been sent to an open air school on account of an ailing and general ill health.

¹ *Blood Pressure in Early Life*. D. J. C. Taylor. Cambridge University Press, 1924.

No 2, now aged 10, has been attending the school clinic for six months for suspected phthisis, and is very delicate and anemic, pressure still very high

No 3, now aged 10, has been recommended for an open-air class owing to ill health, but his parents would not agree, his systolic pressure is now extremely high, being 41 mm above the average for his age

No 4, now aged 11, has been sent to an open-air class owing to general debility, pressure has fallen to 9 mm above the average for his age

No 5, now aged 13, has also been sent to an open-air class for the same reason, pressure has fallen to only 4 mm above his age average

No 6, now aged 14, has remained fit, pressure down to about 7 mm above average

No 7, now aged 14, has remained fit, pressure still high, but now below the suspicious level

No 8, now aged 14, has suffered from quinsy, pressure is still close to the suspicious level

No 9, now aged 13, has gone from specialist to specialist owing to some obscure endocrine disturbance with obesity, pressure remains very high

No 10, now aged 14, has remained healthy apart from tonsillitis, pressure has now fallen almost to average

No 11, now aged 14, has remained healthy, pressure is still high, but now below the suspicious level

The interesting points indicated here are (1) that more than 50 per cent of these boys whom I found two to three years ago to have high systolic pressures but no other symptoms have subsequently fallen into ill health, and (2) that in those ruling boys who have been treated on open-air lines the pressure has fallen, whereas in the others it has continued to increase. For a conclusive proof of the significance of (1), the boys who presented normal pressures should, of course have been examined also, but it is scarcely possible that their medical history could have been of this order. Though this evidence is somewhat slender, it can only be substantiated by further work of the same kind, and I believe it to be sufficient to justify urging the inclusion of blood pressure estimation in the routine school medical examination of children from 10 years upwards. In addition to enabling the beginnings of hyperpnea to be thoroughly investigated (and the school medical officers alone are in a position to do this), and assisting in the detection of cardiac lesions liable to be otherwise missed, such a routine examination would, I believe, provide in an appreciable percentage of children the first warning of an impending breakdown. I suspect, moreover that we shall find that the nervous and toxic factors responsible for this state of affairs may often be successfully combated at this early stage by prescribing open-air treatment in these cases, either in the form of more outdoor exercise, or, where possible, in an open-air class—i.e., etc.

"NEO CARDIOLOGY"

Sir,—Is it not time that the term "neo cardiology" was dropped? It seems to be used to suggest that the investigation of the heart by means of mechanical instruments is the essence of our knowledge of heart disease, and not, as it really is, a mere fraction. I have possessed a polygraph since 1906 and an electro-cardiograph since 1914, and is my first paper on cardiac subjects was published last century I may perhaps be allowed a short space in your columns.

In the early days our knowledge of cardiac disease was derived from examination by the hand and the eye. With the advent of the stethoscope came recognition of the different forms of valvular defect. With the advent of improved pathological technique came recognition of the various kinds of myocardial disease. With the advent of the sphygmomanometer came recognition of variations in the arterial blood pressure. With the advent of the polygraph and the electro-cardiograph came recognition of the different forms of arrhythmia. At present we are beginning to learn something of the changes which may take place in the intrinsic mechanism of the ventricular muscle.

The facts gained by these methods have then value chiefly because they convey a definite meaning to medical men.

There is nothing special in cardiac disease to separate it from disease in other organs. If anyone wishes to learn the response of the heart to infections he will learn it best in the fever hospitals. If he wishes to learn its response to strain and stress he will learn it best in the naval, military, and air services, or in a mining practice, he will not learn it in hospitals for diseases of the heart. But if we wish to learn the utmost about cardiac hearts we must utilize all the methods which give us information concerning the cardiovascular system. The ophthalmoscope is sometimes more important than the stethoscope.

The finger and the eye recognized aneurysms. The ear recognized mitral stenosis. The sphygmomanometer told us when the arteries and the kidneys were damaged. The electro-cardiograph has taught us to recognize bundle branch block. By these methods our present treatment of auricular fibrillation has been evolved. It is perfectly true that Withering was probably cognizant of the same facts, but the absence of instrumental evidence of the nature of the irregularity prevented the acceptance by other members of our profession of the truth of his propositions.

If we do not take a culture in a doubtful case of diphtheria, and so permit a patient to die from his unrecognized toxæmia, we are justly blamed if we do not recognize that a patient with aortic incompetence is suffering from unmeted syphilis we are equally to blame, and if we confound a putrid heart block with auricular fibrillation, and so institute an erroneous line of treatment, we again deserve reproach.

So it seems to me that if we try to pose as men with special knowledge of heart disease we must use all the available means to learn, as precisely as is possible the exact nature of the disturbance which affects our patients' hearts, and we must not confine ourselves, in our practice, to heart disease alone, for it is from our knowledge of the reactions of the heart to general infections, and to local infections in origin other than the heart, that we will become best fitted to afford help to those patients who do us the honour to ask our aid in connection with some definite cardiac lesion.

And I would ask your permission to sign myself

November 28th A GENERAL PRACTITIONER

Sir,—May I be allowed a little of your valuable space to reply to Dr. Donald Hill's letter on this subject in the *BRITISH MEDICAL JOURNAL* of December 12th (p. 1152)? He writes in such a manner that most readers who had not read my letter would think that I advocated a diagnosis of cardiac disease entirely by auscultation, percussion, etc. What I said was that "one must not only take advantage of the information obtainable from the newest and best scientific methods of investigation, such as the polygraph and the sphygmomanometer, but one must also make a careful study of the character of the cardiac sounds, the area of the cardiac dullness and all other physical signs in any way connected with the heart and vessels." Surely his letter bears out my statement that a certain school of cardiologists actually discover investigation of the cardiac condition by such methods as auscultation and percussion.—I am, etc.,

LESLIE THORPE THORNTON

London W 1, Dec. 11th

Sir,—The correspondence on the subject of cardiology is certainly entertaining, and in one way very informing—namely, with regard to a large amount of ignorance which seems to prevail on the subject, for both parties can hardly be right.

Dr. Hill tells us in the most authoritative manner that "the owner of a degenerated myocardium may yet possess normal heart sounds," and as it is still taught at all the medical schools that the first heart sound is produced by the contraction of the myocardium, it seems very extraordinary that the contraction of an abnormal myocardium can produce a normal heart sound.

I heartily agree with the most emphatically expressed statement of Dr Hall, that it is quite impossible to learn anything by clinical examination of the condition of the myocardium—if he still subscribes to such a theory of heart-sound production—I am, etc.,

Swansea, Dec 13th

G. ANTOUR STEPHENS

PUERPERAL SEPSIS

SIR,—We are told by those who specialise in obstetrics that statistics prove that so far as puerperal sepsis is concerned the death rate shows little diminution in the last twenty years. With all humility I beg to challenge this. We all know that statistics are not always reliable and have led us astray on many occasions, if the other facts in the case are not carefully considered.

As a general practitioner of over twenty years' experience I must say that sepsis during the puerperium does not appear to me to be anything like so prevalent since the advent of the trained midwife, with her knowledge of the value of asepsis and general cleanliness.

Is it not a fact that twenty years ago many cases were not looked upon as septic, nor notified as such, which to-day would call forth a good deal of attention and be carefully notified?

I am fully convinced that puerperal sepsis has shown a great diminution in this area during the last twenty years, but, as diagnosis and notification have become keener, the diminution is more real than statistics would indicate. It would interest me to hear the opinion of other general practitioners on this subject, and whether they agree with my view, that in spite of statistics there has been a great diminution in puerperal sepsis during the last fifteen or twenty years, due largely to the clean and aseptic methods of the present-day trained midwife as against the often unclean and insanitary methods of the old-fashioned monthly nurse.

In my own experience I do not find that if one has the assistance of a properly trained midwife that bruising or perineal tears—providing, of course, any tear is attended to at the time—will cause any trouble or risk of temper time afterwards—I am, etc.,

Bridgwater Dec 12th

RICHARD COATES

NEOSALVARSAN IN THE TREATMENT OF PUERPERAL SEPTICÆMIA

SIR,—In your issue of December 12th (pp 1125-26) I am reported to have stated that "Neosalvarsan was the most efficient drug to use" in puerperal septicaemia. As I was particularly careful to avoid saying this I shall be glad if you will correct it, lest it should give rise to expectations which may not be justified. What I actually said was that arsenical drugs of the neosalvarsan type were more likely, in my opinion, to be effective in the treatment of puerperal septicaemia than any other drug at present known to me. This opinion was explained, rests upon the observation that neosalvarsan, after injection into man in the usual antisyphilitic doses, confers upon the blood fluids a considerable power to kill the hæmolytic streptococcus, and that this killing power lasts for many hours after the injection. These observations which will be submitted for publication in full in the near future, seem to me to give legitimate ground for hoping that something may be achieved in the treatment of these septicaemias by the agency of this drug, but they by no means warrant the assumption that it is bound to be effective. Other considerations, clearly, have to be taken into account—for example the slowness of the bactericidal action combined with the rapid excretion of the drug, the possible development of "fastness" of the streptococcus under the influence of the drug, the damage done by the drug to leucocytes or other essential tissues of the patient. Any of these—or other eventualities as yet not clearly seen—may rob us of success.

To enable us to judge what can be done by means of this drug in the treatment of septicaemia it remains for us now to observe a number of cases supplementing the impressions of our unaided senses by records of changes in the number of cocci surviving in the patient's blood, the functional activity of her leucocytes, the killing power of her

serum, etc. Such observations are in progress and will be reported upon. If the conclusion is reached that neosalvarsan is not an effective remedy in septicaemia I, for one, shall not be very surprised, for it cannot be forgotten that the chances seem to be always against any attempt to achieve a big bactericidal coup by the introduction of a chemical agent into such an extraordinarily complex chemical system as the human body.

Meanwhile we may take a little comfort in the reflection that from a much more slender basis of *in vitro* and *in vivo* observations on the effect of arsenous acid upon trypanosomes (Laverin and Mesnil, 1902) there has come, in the course of twenty years, a considerable measure of success in the control of human trypanosomiasis and also, indirectly, Ehrlich's great contribution to the treatment of syphilis.

One more mistake I should like to point out. I am credited with the suggestion that the hæmolytic streptococci of puerperal fever are transformed non-hæmolytic cocci derived from the vagina. What I said was that I knew of no evidence pointing in that direction—I am, etc.,

London W 2 Dec 19th

LEONARD COLEBROOK

AN UNUSUAL ANAESTHETIC FATALITY

SIR,—With regard to the recent anaesthetic fatality (British Medical Journal, October 17th p 713) in which the cause of an explosion of ether vapour and oxygen still remains a mystery, I should like to add one more suggestion before the subject is finally closed.

Owing to the courtesy of my dentist I was able to carry out an experiment with his unactivated lamp and hot air syringe which suggested a somewhat simple explanation of this explosion of anaesthetics. I found that by brushing the burning wick of the lamp with the end of the hot air syringe it was possible to remove a minute burning portion of the wick and transfer it to some considerable distance from the lamp. I also found that by thrusting the end of the syringe into the saturated wick it was possible to remove a drop of burning spirit on the end of the syringe.

I suggest that the explosion of the anaesthetic in question may have been brought about in either of these ways—I am, etc.,

J. N. JONES, M.R.C.S., L.R.C.P.

London S.W.1 Nov 27th

BLOCK GRANTS FOR HOSPITAL SERVICES

SIR,—In the JOURNAL of December 19th you refer to the speech of the Minister of Health at Birmingham on December 12th in which he advocated block grants from the State for voluntary hospitals on the same lines as now proposed for local education authorities—an ominous comparison. You conclude by expressing a hope that this scheme may be initiated as another measure of constructive statesmanship.

The conditions to be attached to this proposal include, as you say, in usual controlling body for all hospitals situated within the area a say in all decisions by the committee of management of a voluntary hospital as regards extensions, new sites and character of building, a requirement to maintain a certain minimum standard of efficiency, a grant to be received by the hospital as a settlement for this State control.

The definition of a "voluntary" hospital has been gradually watered down until it is now taken to mean "the independent and voluntary management." Can anyone conceive the kind of management of a "voluntary" hospital under these conditions—and others gradually imposed on them—becoming in any way dissimilar from a local Board of Management—that is a body of meddling mandarins?

Those who have consistently advocated that all voluntary hospitals as soon as may be should be taken over by the State will welcome the BRITISH MEDICAL JOURNAL's advocacy of this latest proposal.

The support of a voluntary hospital in the past has been due entirely to local interest developed on behalf of that hospital and those using it—namely, the local necessitous poor. But if the rapidly diminishing number of voluntary supporters of hospitals—at present necessarily

worried by hazards, tears, dances, pound div, and so on—
to be compelled by means of taxation to provide funds
for voluntary hospitals generally, which are to be used by
persons whether resident in the district or not who by
means of fees or contributory schemes or otherwise, are
quite able to pay in full for all their requirements; the
result will be probably to give a final blow to charitable
hospital bequests and subscriptions, and to hasten the day
when these institutions will have to be taken over by
the State if they do not wish to become bankrupt.

The Minister of Health would have done a greater service
to voluntary hospitals had he advocated equitable con-
tributory schemes of self-help for both industrial and
middle classes on the principles enunciated in the hospital
policy of the British Medical Association.

The statement by the Minister of Health that "the
growth of population under an increase imperative"
contains a fallacy—a fallacy often used as an incentive
for further cuts on the rich. If preventive measures
(proper housing, town planning, pure milk supply, smoke
abatement, public house reform, etc.) were promptly taken,
it would not be unreasonable to hope that the percentage
bed accommodation now prevalent would be greatly
reduced—I am, etc.,

Bore Dec 21

1 ROWLAND FOTHERGILL

TRIPLANING AND TIEPLINING

Sir,—In the recent discussion concerning the operation
so frequently performed on prehistoric skulls, and which is
still practised by Neolithic people, the operation itself has
been described as tieplaning; this appears to me to be a
misnomer. The tiepline was a special instrument, in-
vented by John Woodall, a distinguished surgeon who died in
1643, and who had been surgeon to St Bartholomew's
Hospital and master of the Barber-Surgeons' Company.
In his *Treatise* published in 1628 he describes his instru-
ment as an improvement on the tieplan and he calls it
a "tiepline" (subsequently "tiepline") although for
some time after Woodall's invention the operation was
called tieplaning (vide *Pepys's Diary* 1666-1667), as
the tiepline came into more general use the word
tieplaning was used to describe it.

Before the invention of the tiepline the operation was
called tieplaning, and the instrument with which it was
performed was called a tieplan or tiepline. The word
tieplan is of very ancient origin (*Ci-typermoi*, a bone),
and in the Middle Ages was applied to any boring
instrument used for the purpose.

The term "tieplaning" is certainly not obsolete, for
it is curious that lay writers generally refer to the modern
operation as tieplaning, while expert writers so frequently
describe the prehistoric operation as tieplaning.

If a generic term is required I think it should be
tieplaning, which might logically include both the
modern and the prehistoric operation, and that it should
always be applied to the latter—I am, etc.,

London N.W. 3 Dec 8th

H. A. CLOWES

THE MEANING OF "CLAUDICATION"

Sir,—I hope I may not be considered unduly pedantic if
I enter a mild protest against the use (or rather misuse)
of the word "claudication" by Professor Stirling. In the
BRITISH MEDICAL JOURNAL of December 19th he is reported
to have used the expression "claudication in the vessels of
the vasomotor centre" (p. 1164), and again, "claudication
of the renal vessels" (p. 1165).

Now claudication, if it means anything means "lame-
ness" or "limping" and is derived from the Latin
claudicare, "to limp," not from *claudere*, "to shut." The
term "intermittent claudication" was first used by Bonley
in 1831 to describe intermittent loss of power in the limbs of
the horse, and Charcot, in 1858, applied the expression to
a similar condition in the human subject. The fact that
claudication is recognized as being caused by occlusion of
the vessels is no reason for regarding the words as
synonymous—I am, etc.,

MAURICE E. SHAW

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

PARLIAMENT was prorogued this week till February 2nd, 1926.
The concluding debates in the House of Commons concerned
the Moral and of the League of Nations, and the Lords
amendments to the Riting and Vilitation Bill, Criminal
Justice Bill, and other measures.

Colonial Medical Services

Dr. Shiels asked the Colonial Secretary, on December 17th,
how much below establishment strength were the medical and
sanitary services of Nigeria, Gold Coast, Sierra Leone, Kenya,
and Tanganyika respectively, what steps were being taken to
fill the vacancies, and who was responsible for recruiting and
selecting the personnel.

Mr. Omsby Gore (Under Secretary for the Colonies) stated
that in the West African Medical Staff at present there were
nineteen vacancies in Nigeria, thirteen in the Gold Coast and
nine in Sierra Leone. Nine selected candidates were receiving
instruction in this country in tropical medicine and eight more
would commence instruction in the new year. There were no
vacancies in Kenya and only one in Tanganyika. The vacancies
and terms of service were advertised regularly in the medical
press and the attention of the universities and teaching schools
was drawn to these services periodically, while advantage was
taken of the presence of senior medical officers on leave in this
country to visit the medical schools and interest the students
in the colonial services. Selection of candidates was made by
the Secretary of State with the assistance of a small sub-
committee containing two medical men of distinction who
advised as to the suitability of candidates interviewed by them.

On December 21st Sir Sydney Henu asked Mr. Amery what
steps were being taken to strengthen the medical services
throughout East Africa, and what was the attitude towards
recruitment in this country for such services adopted by medical
schools and societies. Mr. Amery told Sir Sydney that it was
not possible to give definite figures pending consideration of
the estimates of the various Dependencies for the coming
financial year, but he anticipated that there would be a con-
siderable further extension of medical work in Eastern Africa
in the near future, especially in Kenya, Uganda, and the
Tanganyika Territory. It was hoped to increase the personnel
of the East African Medical Service by some twenty or thirty
officers during the next year. The attitude towards recruit-
ment adopted by the medical schools and societies had been
very helpful in the past and he hoped to secure their co-opera-
tion in filling up the many new appointments which were about
to be created.

Mr. Amery, on December 21st stated that he was aware of
the high rate of mortality in Tanganyika Territory. Active
measures were being taken to improve medical and sanitary
conditions. The number of medical officers had been increased
by twelve this year and numerous native assistants, including
sanitary inspectors were being trained.

Public Vaccination

Answering Mr. Groves on December 16th Mr. Neville Chamberlain
(Minister of Health) said he was not prepared to consider
legislation to amend the Vaccination Acts in such a way that
persons who themselves desired or desired their children to be
vaccinated should apply for such publicly assisted service not
as at present that those who desired exemption should apply.
Awards were still payable to public vaccinators in accordance
with the provisions of Section 5 of the Vaccination Act 1867
on reports made to the Ministry of Health with regard to the
number and quality of the vaccinations performed and it was
provided in the section that any payments so awarded should
be in addition to the payments received by public vaccinators
from the guardians. Asked the average amounts of the special
awards to public vaccinators under Section 5 of the Vaccination
Act 1867 Mr. Chamberlain gave the following as the approximate
average amounts per child vaccinated during each of the past
12 years ended on September 30th: 1919 4.4d, 1920 12.6d,
1921 11.4d, 1922 10.9d, 1923 8.7d, 1924 8.6d. Separate figures
were not available showing the amounts spent on the service
of public vaccinators nor the proportion of vaccinated to unvac-
cinated children under 10 years of age during the last decade. Mr.
Groves suggested in his question that the ratio of exemptions from
vaccination was progressively increasing and the ratio of small pox
deaths correspondingly decreasing. The Minister did not deal
with this.

In a further series of answers to Mr. Groves on December 17th,
the Minister of Health said the expenditure from local rates
on vaccination during the year ended March 31st, 1921 was
£175,000 whereas for the previous year the amount was £124,000.
The increase of expenditure was mainly due to the operation of the
Vaccination Order 1919 which came into force on December 1st

1919 and prescribed an increased minimum fee of 5s payable to public vaccinators for each domiciliary inspection. The minimum fees paid to public vaccinators were (a) One shilling in respect of each child whose name was included in the lists forwarded to the public vaccinator by the vaccination officer (b) Five shillings in respect of each successful primary vaccination performed at the home of the child or person vaccinated and duly recorded in the vaccination register (c) Two shillings and sixpence in respect of every successful vaccination or revaccination performed at the public vaccinator's surgery or elsewhere than at the home of the person vaccinated, and duly recorded in the vaccination register. Very few public vaccinators were paid by salary and there was no standard salary. The amount paid varied according to the circumstances of the district and the work to be done. He was not aware that there were any vaccination officers other than public ones. Of the 122 persons who died of small pox during the ten years ending with 1921, 43 had been vaccinated, 59 had not been vaccinated prior to exposure to infection and in 20 instances the vaccinal condition was doubtful. The 43 vaccinated cases included no person under the age of 12, four persons between the ages of 12 and 25, and four between the ages of 25 and 35, the remainder being in each case over the age of 35. The records showed that only four of the vaccinated cases had been revaccinated, the ages of these persons being 25, 35, 58 and 61 respectively. Of the 59 unvaccinated persons 26 were under the age of 12, 18 between the ages of 12 and 25, 9 between the ages of 25 and 35 and 6 over the age of 35. The percentage of births vaccinated during the period in question was 43.5. In the judgement of Mr Chamberlain's medical advisers, primary vaccination was of great and proved utility. He did not contemplate any measures for an obligation to revaccinate quinquennially. The words about the tragedy of a widespread epidemic of small pox being realized had been omitted at the end of the first paragraph in the 1924 edition of the Ministry of Health pamphlet No. 8 on the subject of small pox and vaccination. These words were omitted in view of the general mildness of the type of small pox in this country at the time the pamphlet was revised. He was aware that the number of deaths in this country attributed to chicken pox during the past twenty years largely exceeded the number of deaths attributed to small pox during that period. This fact did not appear to afford any sufficient reason for reconsidering the present vaccination laws. He had no information showing that the commissioners of national health insurance in Germany had accepted the principle of Government compensation for injuries or ill effects following vaccination.

On December 21st Mr Neville Chamberlain informed Mr Bionfield that statistics relating to small pox cases and deaths in Switzerland were available. The following figures relating to deaths had been obtained from the *Statistisches Jahrbuch der Schweiz* for the years 1915 to 1922, and from the *Bulletin du Service Fédéral de l'Hygiène Publique* for the years 1923 and 1924. The figures relating to cases had been abstracted from the several *Bulletins du Service Fédéral de l'Hygiène Publique*.

Year	Switzerland		Small pox Notifications and Deaths	
	Cases	Deaths	Year	Deaths
1915	4	2	1920	7
1916	—	—	1921	596
1917	—	—	1922	153
1918	2	—	1923	2145
1919	3	—	1924	1274

Ministry of Pensions

Answering Mr Pielou and Mr T. Williams Major Tryon said that any information supplied by a panel doctor concerning one of his pensioner patients was always carefully considered in its bearing on any certificate to be given by an officer of the Pensions Ministry. It was not the case that certificates of panel doctors were ignored, but in Ministry of Pensions work the verdict of the Ministry's medical officer must be final. In reply to Mr Montagu Major Tryon said there were 57 deputy commissioners of medical services of whom five were stationed in the metropolitan area. They were distributed throughout the country and if necessary their distribution was varied in accordance with the needs of the ex-service population. In densely populated districts the deputy commissioners were provided with assistants who numbered thirty in all. Each of the deputy commissioners of medical services was responsible for more than one area, with the exception of the deputy commissioners stationed at Aberdeen, Gloucester, Leicester, Belfast and Bristol. Major Tryon informed Mr Gibbins that of the 26,000 pensioners in receipt of treatment with allowances about 6,600 were inmates of mental institutions. Apart from mental cases many required constant medical attention and strict nursing while others in accordance with medical advice were receiving prolonged institutional treatment and care. Where the medical advisers of the Ministry considered any case could more suitably be dealt with by discharge from institutional care this was done.

Major Tryon (Minister of Pensions) said in answer to Mr Ridford that about 59,000 men were in receipt of pension in respect of a disablement arising from one or other form of chest affection. Rather more than half this number were cases of pulmonary tuberculosis for whom treatment was by statute the concern of the local health authority acting under the Ministry of Health. In sanatorium provision for these cases the climatic factor was always considered. Cases of chest affection other than tuberculosis were where necessary provided for in Ministry institutions situated in various parts of the country and in the event of a change of climate being essential in any individual case transfer from one hospital to another could be effected. The results of treatment of these cases in Ministry institutions did not indicate any need for the setting up of further institutions in

other localities. Approximately £2,500,000 was expended by the Ministry of Pensions on treatment of tuberculous pensioners in sanatoriums during the five years ended March last. In the eleven months ended November 30th last 73,770 cases received treatment with allowances.

Major G. C. Tryon states that the treatment for epilepsy at the Ministry of Pensions Hospital, Maghull, included all the known curative and ameliorative methods. He denied that epileptics from Maghull and neurothesians from other institutions had been informed that they must travel home in crowded excursion trains. Where the journey involved overnight travelling two extra nights' absence may be allowed.

The Ministry of Pensions cannot provide auto wheels for the invalid chairs of permanently disabled men.

Tuberculosis—In the West Riding education authority's area there are three sanatoriums schools providing education for 172 tuberculous children. In 1924 287 tuberculous children from this area were sent to sanatoriums or certified hospital schools. Sir Kingsley Wood, speaking for the Minister of Health, said that a letter had been received from the Henbury Parish Council objecting to the proposal of the corporation of Bristol to use Blaise Castle as a tuberculosis institution for advanced cases. If the corporation made application for the Minister's approval the objection would be considered. The Ministry, however, was advised that there was no ground for considering that a properly conducted institution for the treatment of tuberculosis was in any way a danger to the health of the community in which it was situated and that no risk was incurred by living in the immediate neighbourhood of such an institution.

Mr Davidson (Secretary to the Admiralty) states that naval cases of tuberculosis are invalided by the Board of Survey at naval hospitals. In a very few instances, however, where the patient had already entered a sanatorium, prior to coming under naval observation it might be necessary to hold a survey with a view to invaliding without causing the patient to be moved. This survey might be carried out by the Admiralty surgeon and agent of the district in conjunction with the sanatorium authorities.

Death Rates in England and Wales—Mr Chamberlain has supplied the following table of death rates in England and Wales among men and women separately and among children and young persons of both sexes.

Age Groups	Death Rates per 1,000 Living of Each Sex					
	1922		1923		1924	
	M	F	M	F	M	F
21 and over	16.7	14.7	15.5	13.4	15.2	14.2
Under 5	30.2	24.5	24.3	19.6	22.1	20.2
10	16.5	13.5	14.0	11.3	14.9	12.1
15	11.4	9.4	9.7	8.0	10.3	8.4
20	9.2	7.7	7.9	5.5	8.3	6.9
21	9.0	7.5	7.7	6.4	8.1	6.7

Estimates of population in European countries are not available for the purpose of calculating mortality rates.

Nurse—Mr Duncan asked the Minister of Health if the three nurses who contracted a case of that disease in the Brentford Sanatorium in 1924 as mentioned on page 55 of the annual report of the chief medical officer of the Ministry of Health for the year 1924 had been previously immunized against that disease in any way and whether any of the cases proved fatal. Mr Chamberlain said the answer to both parts of the question was in the negative. One of the nurses seven months before attending the case referred to had received a dose of diphtheria antitoxin but this dose would not confer immunity for more than one month after it was administered.

Proposals for Amalgamation of Medical Services—The Prime Minister informed Sir F. Sykes on December 21st that the question of the amalgamation of the medical branches of the three fighting services was carefully considered by the Government some two or three years ago when it was decided that it was undesirable to set up a committee to consider the possibility of reorganization. A Standing Joint Committee on which the Ministry of Pensions Medical Department was also represented had been set up to discuss matters affecting the medical services of the four departments. The question of the pay of officers of the medical branches of the three fighting services and all matters ancillary thereto was at present being considered by a committee set up for the purpose.

Bethlem Hospital Bill—The House of Commons has given its promoters of the Bethlem Hospital Bill special facilities for reintroducing it next session and ordered that if they gave notice of reintroduction before the end of the present session the proceedings on it should be *pro forma* only in regard to every stage through which it had passed in the present session. The House of Lords through which the bill has already passed concurs in this arrangement. In proposing it to the House of Commons the Chairman of Committees said the Bethlem Hospital Bill had been objected to from time to time and he had adjourned it in the hope that some settlement might be arrived at. No settlement had been arrived at but he had some hope that if it were adjourned till next session, a settlement might be reached.

Insurance Dental Benefit—On December 21st Mr Neville Chamberlain told Mr. Waite that the specifications issued to approved societies by the Public Dental Service Association which represented the results of negotiations between representatives of the dental profession and of certain approved societies, did not require and had not received any recognition from his department. He had no power under the existing Acts to make regulations ensuring dental treatment and dentures of a standard price and quality as in the case of medical benefit. He was advised that having regard to the terms in which dental treatment was defined in the Acts, it was not a benefit in the nature of medical benefit.

Opium and Cocaine in India—On December 21st Lord Winterton (Under Secretary for India) informed Mr. Thurtle that under the Protocol to the Geneva Convention a commission would be appointed by the Council of the League of Nations to decide at the end of five years whether control in the signatory countries was sufficient to prevent completely the smuggling of opium from constituting a serious obstacle to the effective suppression of the use of prepared opium in those territories where such use was temporarily authorized. The Protocol had been accepted by the Government of India. On December 21st Lord Winterton said that entire reports of prosecutions in Bombay for the illicit sale of cocaine were not officially received except of the arising from Customs seizures at the ports which were required for communication to the Secretariat of the League of Nations. He had seen reports in the press of recent cases in which convictions were obtained.

Sealed Milk Cans—On December 21st Sir Kingsley Wood told Mr. H. Williams that the Minister of Health had received a number of suggestions that a Milk and Dairies Order should be issued for the sealing of milk cans. The Minister was in the matter.

Housing—During a debate on the Government's housing policy which the Labour party initiated on December 18th Mr. Neville Chamberlain said that over 159,000 houses had been built this year and the production was still increasing. An enormous amount of repairs and renovations was also being done. In the single year 1923 the number of houses put into habitable condition was 512,087. He indicated that local authorities might be given power to acquire houses compulsorily and to make it habitable until they were ready to rebuild. The possibility of improving existing houses in rural areas should also be considered. Since 1919 the number of houses built in rural districts was 161,460. Mr. Baldwin announced that the special subsidy of £40 offered for houses built of alternative materials in Scotland was withdrawn. Instead the Government had decided to undertake the construction of two thousand houses in Scotland by alternative methods. Mr. Frennville said Parliament had sufficient powers at present to solve the housing problem. People must be housed near their work. Artificial roads could not be opened to keep pace with the increase in motor and the congestion on the railway lines was increasing. To get people close to their work tenements must be built. The experience of the London County Council was that some people preferred them. In London it would be advisable to rehouse on the Tabard Street area by buildings five stories high surrounding an open space of five acres. Workers in many trades did not require to remain in the towns but it was a melancholy spectacle to see factories being moved out of London without provision being made for the workers. It was necessary to have a special train daily to bring the workers from London to one model factory at Greenford. The aim of the House of Commons should be the erection of new towns on properly selected sites. An example was afforded by Welwyn. The Trade Facilities Act was available for factories moving out into the country. There should be a revolt against the development of the suburb.

Recent Areas and Infant Mortality—In a debate on recent areas on December 16th Mr. Lansbury said they had heard that in one area 50 babies more per 1,000 were dying. He returned to the subject in a question to the Prime Minister on the following day, suggesting a correlation between the rate of infant mortality and the local rate of outdoor relief. Mr. Lansbury renewed his suggestions on December 21st in a question to Sir Kingsley Wood who said it was clearly necessary to secure a reasonable measure of economy in areas in which special financial difficulty had arisen.

Notes in Brief

The Government has not yet decided whether a Child Adoption Bill shall be brought in next session.

The Ministry of Health is unaware of any instance where an excess of arsenic has been found on Australian apples.

The question of economies in the Ministry of Health is under consideration by the Cabinet Economy Committee.

On October 31st 1925 216,969 persons were receiving institutional relief in England and Wales and 1,053,210 domiciliary relief. On the corresponding date in 1924 the numbers were 211,802 and 834,918.

The Board of Trade cannot distinguish between the imports of boracized and unboracized bacon and hams.

On December 15th Lieut. Commander Kenworthy presented a petition from 2,567 residents in Folkestone praying that the practice of vivisection might be discontinued.

The Minister of Health has raised no objection to a proposal by the Thetford Rural District Council to appoint a fully qualified sanitary inspector at a salary of £200 a year.

Universities and Colleges

UNIVERSITY OF OXFORD

At a congregation held on December 17th the following medical degrees were conferred:

D.M.—M. H. Mackeith
D.M.—C. W. Simpson L. J. Barford F. J. Bach A. Chilton S. Howard
V. H. Brink

The following candidates have been approved at the examinations indicated:

First B.M.—R. G. ...
L. J. Brink
Gardner
D. O. W.
Medic ...
S. B. Davis J. L. Glover R. E. Hayward I. R. Holdday H. E. Mansell
A. J. M. Melly (Pathology) M. D. Bower V. H. Brink C. L. Copp
W. N. Dickenson O. Hooper W. H. Hudson R. Lingworth A. J.
Leslie Spinks R. G. MacGregor R. Oddie D. I. Ree Grace Batten

Simpson A. G. Wilson E. M. Wright Margaret N. Jackson
Constance I. Patullo

UNIVERSITY OF CAMBRIDGE

Chair of Physiology

Mr. JOSEPH BARCROFT M.A. F.R.S. Fellow of King's College has been elected to the chair of physiology in succession to the late Professor Langley. Professor Barcroft was born in 1872 and went to school at York and the Leys Cambridge. After obtaining the B.Sc. Lond. degree he went up to King's with an exhibition in 1893 and gained first-class honours in Parts I and II of the Natural Sciences Tripos, graduating B.A. in 1896. He won a Walsingham Medal in 1899 and the Gedge Prize for original research in physiology in the following year. He was elected F.R.S. in 1910 and received a Royal Medal in 1922. As Oliver Sharpey Lecturer before the Royal College of Physicians of London in 1915 he took for his subject a comparison between some physiological and pathological conditions. A report of these lectures was published in the BRITISH MEDICAL JOURNAL at the time (1915) pp. 713 and 760. The Baly Medal was awarded to him in 1923. He was president of the physiological section of the British Association in 1920. For many years he was a demonstrator and lecturer in the Physiological Department at Cambridge, and since 1919 has been Reader in Physiology. He is also Fullerian Professor at the Royal Institution. During the war he did valuable experimental work as a member of the Chemical Warfare Committee of the Ministry of Munitions and for these services in the course of which he lost health and life he was made a C.B.E. in 1918. Professor Barcroft's many communications to the Royal Society and papers in the *Journal of Physiology* and elsewhere have included reports on the observations made during his expedition to the Andes in 1922 upon the effect of high altitudes on the physiological processes of the human body.

At a congregation held on December 19th the following medical degrees were conferred:

M.B. B. Chm.—A. F. D. Darlington G. A. Back J. P. Malpas W. G. S.
Brown H. W. Fiddison
B. Chm.—A. W. F. Wing E. J. F. Torham

UNIVERSITY OF WALFS

WELSH NATIONAL SCHOOL OF MEDICINE

It will be remembered that about a couple of months ago the Council of the University of Wales decided to apply to the Privy Council for a charter incorporating the Welsh National School of Medicine as an independent school of the University on the lines of the draft scheme which has been before the University for some time or more but that before presenting the petition a conference should be held between the councils of the University of Wales and the University College of South Wales and Glamorgan. At the meeting of the council of the College last week it was decided that it should take part in the conference as a General Purposes Committee without committing itself to any action—that is to say, it will report back to an ordinary meeting of the council. The conference is expected to take place in January.

At the same meeting of the council a College diploma in biology was instituted in accordance with the scheme approved by the Senate and on the report of the Board of Medicine the following appointments were approved: Dr. R. D. Passer M.C., D.P.H., lecturer in pathology and Mr. T. G. Hillyard James M.B. B.Ch., assistant in the surgical unit.

UNIVERSITY OF LONDON

PROFESSOR A. V. HILL Sc.D. F.R.S. has on his appointment by the Royal Society to a Pontefract Chair resigned the Jodrell Chair of Physiology tenable at University College, London. He will carry out his research work at University College and the Senate of the University has resolved that he shall continue to hold the title of Professor of Physiology in the University of London in respect of the functions to be discharged by him at that college.

Dr. W. L. Gye has been awarded the William Julius Wickle Fellowship for 1926 in respect of the work which he has carried out during the past five years.

at the Perth Royal Asylum in Scotland, and in the following year he was appointed physician superintendent of the Ashburn Hill Private Mental Hospital in New Zealand. In 1904 he relinquished this post, and became deputy inspector general of mental hospitals. He was promoted to inspector general in 1907, and retained the position until his death. Dr. Hay was also a member of the National Provident Fund Board and the Prisons Board. He was a member of the British Medical Association, and contributed to the *Journal* and also to the *Journal of Mental Science*.

Dr. PETER HAMILTON ROBERTSON, who died at Hātutū, Wellington, New Zealand, on July 10th, at the age of 49, received his medical education at Glasgow, where he graduated M.B., Ch.B. in 1903, and obtained the diploma of F.R.C.P.S. in 1920. After experience in resident appointments at the Glasgow Maternity and Fever Hospitals, and at the Sussex General Hospital, he was appointed assistant to the Regius Professor of Surgery at Glasgow, Sir William MacEwen, and held that post for five and a half years before the war. His other appointments included those of extra dispensary surgeon to the Victoria Infirmary and to the Royal Infirmary, Glasgow. After the outbreak of war he obtained a temporary commission in the R.A.M.C., and acted during the later stages as surgeon specialist. He then started practice in Hātutū, and was elected to the surgical staff of the Wellington Hospital. He was a member of the Wellington Division of the British Medical Association. Dr. Robertson leaves a widow, his brother, Dr. Alexander Robertson, is in practice in Wellington.

At the memorial service for the late Sir Richard Douglas Powell, Bt., M.D., held at All Saints' Church, Margaret Street, W., on December 18th, Lord Dawson represented the King, and Mr. Bishop Harman, Treasurer of the British Medical Association, represented the Association.

Medical News.

The autumn dinner of the Irish Medical Schools and Graduates Association was held at Pugin's Restaurant, London, on December 18th under the chairmanship of the President Surgeon Vice Admiral Joseph Chamberlains C.B., C.M.G., Director General of the Medical Department of the Navy. In reply to the toast of 'The Guests' which Dr. J. Gubbins FitzGerald proposed, the Right Hon. Charles A. O'Connor, Judge of the Supreme Court of the Irish Free State, gave some recollections of medical dinners in Dublin. Though the Irish medical profession was passing through a grave crisis he hoped that some compromise would be reached whereby those who had been students in the Irish medical colleges would be able to continue to give to England the advantage of the services of Irish doctors. The chairman, in reply, believed that there would yet come about a united Ireland, whose prosperity, happiness, and good government would be the envy of other countries. From his earliest days in Trinity College, Dublin, he had been a student of history, which was still the study of his leisure moments. It filled him with pride that on every page of the story of the British Empire were the names of distinguished Irishmen—diplomats, soldiers, and pioneers. He hoped that the Irish would never forfeit their heritage in that Empire. He had now served for nearly forty years in the medical department of the British Navy; he had been all over the world, and wherever he had gone he had found the Irish to the fore. Speeches full of Irish wit and reminiscence were made by Dr. William Douglas and others.

A FAREWELL dinner was given on November 14th to Dr. Charles Porter, medical officer of health for Johannesburg since 1901. We announced his retirement from this position on December 5th. The chairman, Sir William St. John Carr, described the nomination of the present municipal council in 1901 by the late Lord Milner and the active work of Dr. Porter in its health administrative work since then. Dr. Porter, in reply, gave an account of the various steps taken during his twenty-four years' period of service, including the enlargement of the municipal boundaries, the acquisition of waterworks, improvements in sanitation and the campaign against plague in 1904.

THE next course for the diploma in psychological medicine at the Bethlem Royal Hospital, S.E.1, will commence on January 4th, 1926. Two courses for the diploma are held annually at this hospital. A course is divided into two parts. Part A deals with lectures and demonstrations on the anatomy, histology, and physiology of the nervous system, and Part B deals with neurology, psychological medicine and mental deficiency. The fee for the whole course is 15 guineas, or for Part A or Part B 10 guineas. In addition to the above, clinical instruction in psychological medicine is given at the Bethlem Royal Hospital every morning (Wednesdays excepted) at 11 o'clock. The fee to post graduates for a period of three months is 5 guineas, but a reduction is made to those taking the D.P.M. course. Further particulars may be had from the Physician Superintendent, Bethlem Royal Hospital, S.E.1.

THE Central Association for Mental Welfare (24, Buel Ingham Palace Road, S.W.1) has arranged a course of eight medical lectures on mental disorders and their early treatment to be given by Drs. Thomas Benton, Edward Mapother, and E. A. Hamill on Pearson at 92, Victoria Street, S.W., on Wednesdays at 5.30 p.m., beginning January 6th, 1926. The lectures are intended especially for social workers interested in mental welfare.

THE annual report of the Gordon Memorial College, Khartoum for 1924 describes the very satisfactory progress of the different departments of the school. Certain boys who have completed the secondary course at the Gordon College are now being trained for the medical profession at the Katherine Memorial School of Medicine and this new denture has met with very considerable success. The report contains in account of the research work at the Wellcome Tropical Research Laboratories. Additional laboratories have been established at the Gezira Research Farm and at Atbara for investigations in soil chemistry as applied to cotton growing and for work in connexion with the ulcers and sterility departments. The routine bacteriological examinations during the year amounted to 7,433—a record figure. In addition to agricultural researches, investigations into the life history of bilharzia have been continued, and active steps have been taken for the eradication of this disease. Other studies include the bacteriological typing of the local pneumococci, Kahn's flocculation test for syphilis and various blood diseases.

THE December number of the *World's Children* contains a description by Dr. Katherine S. Macphail, surgeon superintendent of the Anglo-Serbian Children's Hospital in Belgrade of the work performed by this hospital since its foundation immediately after the armistice. During the last seven years more than 37,000 outpatients and 3,000 inpatients have received treatment. In 1921 and 1922 there were temporary convalescent homes in connexion with the hospital. The Serbian Government contributes nearly one half the cost of upkeep and the present English staff is engaged in training the permanent Serbian staff. In the same issue appears an account of the uterine sunlight treatment for children at the South Highgate Infant Welfare Centre of the St. Pancras Borough Council.

A SUPPLEMENT to this month's issue of *Conquest and Healing*, the organ of the Medical Missionary Association of London, states that at the present moment there are in the mission field 463 medical missionaries holding British degrees or diplomas, and that of this total 181 are women. The Church Missionary Society heads the list with 79, the United Free Church of Scotland comes next with 69, while third and fourth are the Wesleyan Missions with a total of 43, and the London Missionary Society with 33.

THE November number of the *Iyeguchi Tieshi*, which is the organ of the Society of the Medical Practitioners of the Orient, Slavonia, and Medjugorje at Zagreb, is devoted to the commemoration of the thousandth anniversary of the foundation of the Kingdom of Croatia. Special articles in English, French and German are published in addition to others in the national language and include an account of a successful hypospadias facial ectodermosis, the hematological diagnosis of Hodgkin's disease, the treatment of hydatid cysts, sarcoma of the orbit and an illustrated article on the four institutions in the country for the treatment of insured patients.

THE chain of children's diseases at the Nancy Faculty of Medicine has been converted into a chain of therapeutics which will be occupied by Dr. Maurice Perrin.

In memory of the late Professor Bergonié it has been decided to found in Bordeaux a laboratory for electrical and radiological research with possibly the creation of a fund to give grants to research workers and to assist radiologists suffering from the effects of radium and x-rays. The treasurer is Dr. H. de Rothschild, 6 rue Saint-Louis du Ronle Paris.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 224
